# Infantile hypercalcemia and CYP24A1 mutations

Filomena Cetani<sup>1</sup>, Daniele Cappellani<sup>1</sup>, Alessandro Brancatella<sup>1</sup>,  
Glenville Jones<sup>2</sup> and Claudio Marcocci<sup>1</sup>

<sup>1</sup>Department of Clinical and Experimental Medicine, Unit of Endocrinology, University of Pisa, Pisa, Italy <sup>2</sup>Department of Biomedical and Molecular Sciences, Queen's University, Kingston, ON, Canada

## OBJECTIVES

- To explain the history and nomenclature for vitamin D–related hypercalcemias.
- To describe the molecular genetics of CYP24A1 mutations.
- To outline the role of CYP24A1 in vitamin D metabolism and biochemical mechanism for CYP24A1-mediated hypercalcemia.
- To delineate the clinical symptoms, diagnosis, and therapy of CYP24A1-mediated infantile hypercalcemia.

## 1. Introduction

Infantile hypercalcemia due to CYP24A1 mutations is reported on the Online Mendelian Inheritance in Man compendium (OMIM, #143880) as a rare condition presenting with failure to thrive, vomiting, dehydration, nephrolithiasis/nephrocalcinosis, and, eventually, death.

Idiopathic infantile hypercalcemia (IIH) is a historical term still used to encompass different conditions characterized by early-onset acute hypercalcemia, often leading to a serious clinical picture. From the first independent descriptions of IIH in 1952 by Fanconi [1] and Lightwood [2], its pathophysiology has been extensively studied, and specific loss-of-function mutations in CYP24A1 [3] and SLC34A1 [4] genes, as well as the Williams-Beuren syndrome [5], have been identified as

possible causes of IIH. As a consequence, since the term IIH is nowadays considered a misnomer [6], the new terms infantile hypercalcemia-1 (HCINF1) caused by CYP24A1 mutations and infantile hypercalcemia-2 (HCINF2) caused by SLC34A1 mutations have been proposed.

The cytochrome-P450 24 subfamily A member 1 (CYP24A1) gene encodes for 24-hydroxylase enzyme responsible for the catabolism of both 25-hydroxyvitamin D<sub>3</sub> [25(OH)D<sub>3</sub>] and 1 $\alpha$ ,25-dihydroxyvitamin D<sub>3</sub> [1,25(OH)<sub>2</sub>D<sub>3</sub>] [7] (reviewed in Chapter 5). CYP24A1 loss-of-function may result in increased serum 1,25(OH)<sub>2</sub>D<sub>3</sub> and calcium concentrations associated with low-to-undetectable parathormone (PTH) [8].

Hypercalcemia is a common condition, with an estimated prevalence of 1/500 patients in the outpatient setting [9]. Hypervitaminosis D as a cause of hypercalcemia is often due to vitamin D intoxication and granulomatous diseases, rather than abnormalities of vitamin D metabolism [8]. During the past 10 years, the increased awareness of IIH has led to an increased number of reports of hypercalcemia due to CYP24A1 mutations, resulting in a large literature mainly consisting of case reports or small case series that bring to light many aspects of the disease not available when initially described.

## 2. Historical notes

Following the first descriptions by Fanconi and Lightwood [1,2], more than 200 cases were reported in Great

Britain over 2 years. Original metabolic studies in IIH patients identified increased intestinal calcium absorption and renal calcium excretion [10], which was attributed to an intrinsic sensitivity to vitamin D [11]. When the British Pediatric Association recommended reduction in the dosage of vitamin D in fortified milk products [12], the incidence of infantile hypercalcemia in the United Kingdom significantly declined [13]. Similar findings were reported in other countries using high vitamin D dosages for rickets' prevention (i.e., German Democratic Republic [14] and Poland [15]), but not in the United States, where lower doses of vitamin D were given during infancy [16], suggesting a dose–effect relationship.

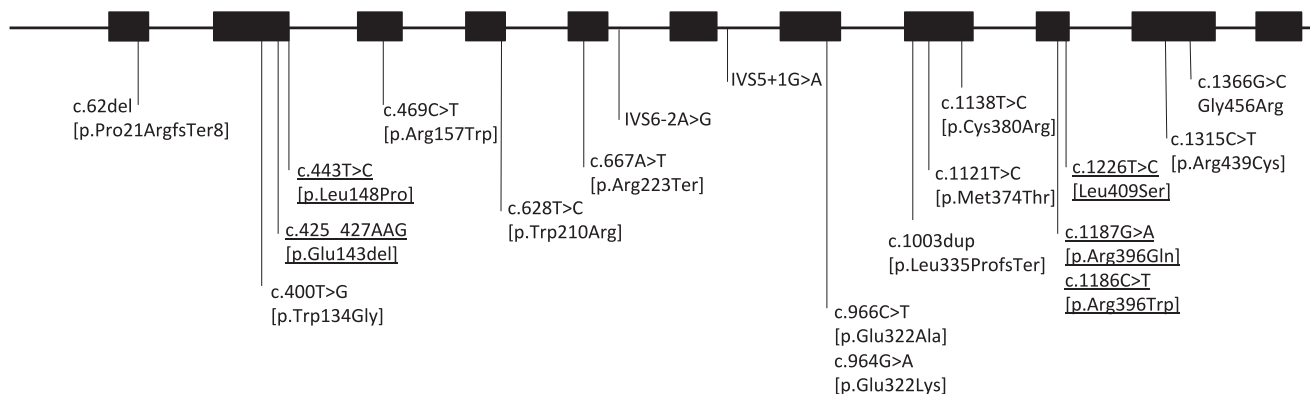

Interestingly, some patients described in the earliest reports presented, in addition to the symptoms of severe hypercalcemia, congenital cardiac abnormalities and an “elfin-like” facies. Accordingly, two different phenotypes were described, namely, “mild” cases, or Lightwood-type IIH, and “severe” cases, or Fanconi-type IIH. Subsequently, when Williams [17] and Beuren [18] independently reported a syndrome (nowadays named Williams–Beuren syndrome) characterized by supravalvular aortic stenosis, peripheral pulmonary artery stenosis, mental retardation, dental abnormalities, and a peculiar facies, it was associated with the Fanconi-type “severe” IIH [19]. Only about 30 years later, the Williams–Beuren syndrome was associated to large deletions on chromosome 7q11.23; this is responsible for the cardiovascular manifestations due to the deletion of the *ELN* gene encoding elastin [20], and, possibly also of vitamin D metabolism impairment due to deletion of other genes on the same chromosome with a mechanism yet to be elucidated [21,22].

At that time, conversely, the pathophysiology of the “mild” Lightwood-type IIH remained unknown, even though the description of family studies suggested its genetic nature [23,24]. Only in 2011, recessive loss-of-function mutations in *CYP24A1* were described in these

patients [3] as the cause of the disease. This mutation was identified using a candidate gene approach, which included *CYP27B1* (1 $\alpha$ -hydroxylase), *CYP24A1*, *FGF23*, and *KL* (klotho). Nonsense or missense loss-of-function biallelic mutations of the *CYP24A1* gene were identified in most patients [15,25–27], including those of the historic cohorts previously diagnosed with IIH [15,27]. A few years later a mutation in the *SLC34A1* gene, encoding the renal sodium phosphate cotransporter 2A, was reported as another possible cause of infantile hypercalcemia in patients resulting without *CYP24A1* mutations [4].

### 3. The genetic basis of the disease: molecular genetics of CYP24A1 mutations

The *CYP24A1* 24-hydroxylase belongs to the cytochrome-P450 superfamily, subfamily A, member 1. This enzyme is encoded by the *CYP24A1* gene, which is located on chromosome 20, position 20q13.2 [28]. This gene is expressed in the whole body, with a particular abundance in kidney, placenta, bladder, and endometrium [29]. Following the discovery that *CYP24A1* mutations were a cause of IIH [3], sequence variations or pathogenic variants in the same gene were identified worldwide [30]. The spectrum of mutations includes missense single-point mutations, nonsense single-point mutations, frameshift mutations (small insertions or deletions leading to a shift in the reading frame of translation), and large deletions of entire exons. These mutations occur all along the *CYP24A1* gene, including the coding exons and in the adjacent splice sites. Fig. 69.1 depicts the distribution of the most frequently encountered pathogenic variants [30]. A recent systematic review and metaanalysis of 50 studies/reports published by the end of 2020 identified biallelic mutations (either homozygous or compound heterozygous) in 61.5% of patients and monoallelic variants in the remaining 38.5% [25]. It is still debated whether the disease

**FIGURE 69.1** Distribution of the pathogenic variants of the *CYP24A1* gene most frequently reported in the literature. The pathogenic variants encountered at least in the 5% of the patients reported before December 31, 2022, are underlined. Modified from Ref. [30].

should be considered as inheritable with an autosomal recessive or dominant pattern. Some authors suggested an autosomal recessive inheritance given the absence of clinical manifestation in patients harboring monoallelic mutations [31,32]. Conversely, other authors, who identified an overt phenotype in these patients, suggested a dominant inheritance pattern [33,34]. Recent studies, which also included subjects wild-type for CYP24A1 mutations, identified an “intermediate” phenotype in patients carrying monoallelic CYP24A1 as compared with biallelic carriers [35], and suggested a “dose–effect” relationship [25,36].

The most common CYP24A1 pathogenic variants are p.Glu143del and p.Arg396Trp, which were associated with infantile hypercalcemia since the first identification of CYP24A1 loss-of-function [3]. These mutations account for about half of the reported pathogenic variants [25]. P.Leu409Ser and p.Leu148Pro are less common (9%

and 5%, respectively), and other variants were mostly anecdotal, often reported once or twice [25].

The prevalence of CYP24A1 mutations in the general population is unknown, since epidemiological data are scarce: an early study reported minor allele frequencies varying from 0.001 to 0.075, with an estimate of total deleterious minor allele frequency of 0.140 [26]. The allelic frequencies for the pathogenic variants estimated by The Genome Aggregation Database (gnomAD) in the aforementioned systematic review and metaanalysis varied from 0.000003977 to 0.008697 [25].

#### 4. The pathophysiology of the disease: mutated CYP24A1 in the vitamin D metabolism

The CYP24A1 gene encodes for a 24-hydroxylase involved in the catabolism of vitamin D (Fig. 69.2)

**FIGURE 69.2** 24-Hydroxylase and vitamin D metabolism. Continuous arrows indicate the physiologic catabolic route, whereas dotted arrows indicate an alternative catabolic route induced by rifampin. Modified from Ref. [30].

(described in more detail in Chapter 5). Vitamin D<sub>3</sub> is hydroxylated in position 25 to 25(OH)D<sub>3</sub>, which is further hydroxylated in position 1 to 1,25(OH)<sub>2</sub>D<sub>3</sub>. CYP24A1 is responsible for the 24-hydroxylation of both 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub>, which is the first step in their catabolic pathway to 24,25(OH)<sub>2</sub>D<sub>3</sub> and 1,24,25(OH)<sub>3</sub>D<sub>3</sub>, respectively [7,8,28,37]. An impairment in this step leads to an increase in serum 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> concentrations. This causes an increase in serum calcium and, to a lower extent, phosphate and a reduction in serum PTH, resulting in a form of vitamin D-dependent hypercalcemia [8].

A CYP24A1 knockout mouse model was generated even before the involvement of this gene in the human infantile hypercalcemia [38,39]. This animal model mimics the phenotype and biochemical parameters of the human disease. These mice have a very high lethality rate during the early infancy and display low baseline 1,25(OH)<sub>2</sub>D<sub>3</sub> levels, a potential compensatory mechanism to prevent vitamin D activation. Both alternative pathways for 1,25(OH)<sub>2</sub>D<sub>3</sub> catabolism by CYP3A4 or a downregulation of 1 $\alpha$ -hydroxylase were suggested [38]. Recently, a knock-in mouse with the R396W mutation of CYP24A1 was generated to further explore the deleterious effects of the most common human mutation as a humanized preclinical model [40].

After the discovery of CYP24A1 mutations, functional studies shed light on the effects of 24-hydroxylase loss-of-function on vitamin D metabolism. Studies using wild-type and mutant CYP24A1 constructs expressed in a mammalian cell line (V79-4, Chinese hamster lung fibroblasts devoid of CYP24A1 activity) confirmed, by measurement of 24-hydroxylated vitamin D degradation products by high performance liquid chromatography, the clinical relevance of the identified mutations [3,32,39].

Additional important information came from the measurement of CYP24A1 activity in vivo by measurement of serum 24-hydroxylated vitamin D metabolites by liquid chromatography/mass spectroscopy (LC-MS/MS) [41]. Several vitamin D metabolites, including 25(OH)D<sub>3</sub>, 1,25(OH)<sub>2</sub>D<sub>3</sub>, and 24,25(OH)<sub>2</sub>D<sub>3</sub>, can be measured, and the 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> can be used as a surrogate parameter for CYP24A1 activity [42].

## 5. Clinical features

In the classical description by Lightwood, hypercalcemia presented in the early infancy, leading to failure to thrive, polyuria/polydipsia, vomiting, dehydration, nephrolithiasis/nephrocalcinosis, and, eventually, death [2].

The age distribution at diagnosis was recently reported to be bimodal, with a first peak in the early

infancy mostly in the first year of life, and a second peak in the adulthood [25]. Most patients with an overt clinical phenotype showed biallelic CYP24A1 mutations, whereas monoallelic variants were often found in relatives of index cases [31,32].

Two phenotypes occur in patients with biallelic mutations: an “early-infancy phenotype” and a “late-infancy/adulthood phenotype.” The former, particularly when presenting in the first year of age [25], is much more severe and characterized by the clinical manifestations of acute hypercalcemia, as originally described by Lightwood. The latter, more often reported in older infants and adults, mostly consists of mild-to-moderate hypercalcemia, recurrent nephrolithiasis (88% of the patients), and nephrocalcinosis (64.7% of the patients) [6,25,32]. The age-related phenotypic switch was early observed and ascribed to the development of tissue resistance to vitamin D, which blunts the hypercalcemic response in the adults but not in the infants [27].

An important issue of the “adulthood phenotype” relates to pregnancy [43–48]. Pregnancy is accompanied by a physiological perturbation to vitamin D homeostasis, especially during the third gestational trimester, when the serum 1,25(OH)<sub>2</sub>D<sub>3</sub> concentrations increase due to enhanced activity of renal and placental 1 $\alpha$ -hydroxylase [49]. The simultaneous inability to enhance the activity of the placental 24-hydroxylase due to CYP24A1 loss-of-function results in an imbalance between the active vitamin D metabolites and its catabolites [50] (see Chapter 34), which may lead to severe consequences. A recent systematic review reported symptomatic hypercalcemia in the 80% of pregnancies [25], more often presenting during the third trimester, and sometimes even in the postpartum period [43,44]. Clinical pictures of gestational hypercalcemia included neurological (confusion [44], altered mental status [48], and seizures [43,45]) and cardiological manifestations (gestational arterial hypertension, preeclampsia/eclampsia [43,50,51], and rhythm disturbances [43,48]), and two pregnancies complicated by acute pancreatitis [47]. As an outcome, it was reported a 10% rate of spontaneous abortion [25], higher than that observed in the general population according to age and gestational weeks, was reported [52,53]. Therefore, it seems safe to suggest a careful counseling before planning of the pregnancy and an accurate monitoring during the entire pregnancy and the postpartum. Interestingly, female homozygous CYP24A1 (–/–) mice abort their pregnancies [39].

An area of current debate is whether carriers of monoallelic CYP24A1 mutations have a clinically relevant phenotype. With few exceptions [33], monoallelic carriers were reported as clinically unaffected relatives of patients with biallelic CYP24A1 mutations. Interestingly, a recent systematic descriptive review reported that in

this setting, one patient over five presented an overt clinical phenotype, even though patients carrying monoallelic mutations displayed a significantly different biochemical phenotype compared with their biallelic counterparts. In particular, nephrolithiasis was present in the 19.4% and nephrocalcinosis in the 4.9% [25] of cases. Such rates were definitely higher than those reported in the general population [54]. The major limitation in addressing this issue is the lack of case–control studies, analyzing differences between carriers of monoallelic and biallelic *CYP24A1* mutations and wild-type subjects. A recent study within a single family suggests that monoallelic carriers present an “intermediate” phenotype between biallelic carriers and wild-type subjects [35]. One possible explanation is that monoallelic carriers might express an overt clinical phenotype (e.g., symptomatic nephrolithiasis) when exposed to triggering factors, namely a vigorous vitamin D supplementation, sunlight exposure, or pregnancy.

## 6. Diagnosis

The diagnostic approach to *CYP24A1* mutations may be challenging, especially outside the setting of acute hypercalcemia [6]. The diagnostic workup requires a thorough personal and family medical history and a comprehensive laboratory testing. Patients harboring biallelic *CYP24A1* mutations present a PTH-independent hypercalcemia highly variable in its severity, but generally mild outside the settings of early infancy and pregnancy [25]. Hypercalcemia is usually associated with hypercalciuria and normal serum phosphate [25]. Seasonal variations in serum calcium concentrations have been reported [35,55], although this aspect has not been taken into account in most reported patients [25]. Serum 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> concentrations displayed a high variability: both analytes are frequently in the normal reference range established by the respective laboratories [25], but are often close to the upper normal ranges established by the National Health and Nutrition Examination Survey [56] and by the Institute of Medicine [57]. Conversely, serum 24,25(OH)<sub>2</sub>D<sub>3</sub> is more often reduced. Nevertheless, since 24,25(OH)<sub>2</sub>D<sub>3</sub> may depend on vitamin D status, the use of the serum 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> ratio is considered a more accurate parameter than serum 24,25(OH)<sub>2</sub>D<sub>3</sub> per se for detecting *CYP24A1* dysfunction [41]. The normal 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> ratio is below 25; ratios above 80 are indicative for *CYP24A1* mutations [41,42,58]. Vitamin D–deficient individuals might exhibit 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> ratio between 20 and 50. A note of caution regards patients with chronic renal failure, who may present low levels of serum 24,25(OH)<sub>2</sub>D<sub>3</sub> concentrations and, therefore, high

25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> ratios. 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> is nowadays recognized as a valuable screening tool for the identification of affected patients, even though it has a negligible value in the identification of monoallelic carriers: as a matter of fact, subjects carrying monoallelic mutations often exhibit 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> values within the normal range [32,33]. These findings are also supported by data obtained in *CYP24A1* knockout mice where pathologic 25(OH)D<sub>3</sub>:24,25(OH)<sub>2</sub>D<sub>3</sub> ratios are found only in homozygous knockout state [59]. Once the diagnosis is suspected, the gold standard for the confirmation is the genetic testing [3].

Hypercalcemia due to *CYP24A1* mutations requires a careful differential diagnosis with other more common forms of hypercalcemia, including primary hyperparathyroidism, familial hypocalciuric hypercalcemia, and other types of PTH-independent hypercalcemia such as paraneoplastic hypercalcemia, granulomatous diseases, and vitamin D intoxication. Table 69.1 shows a schematic representation of the diagnostic workout for the differential diagnosis of hypercalcemia. The diagnostic process may be troublesome for the following reasons: (1) hypercalcemia may be mild outside triggering moments; (2) first-line lab evaluations may provide no clear clues; (3) the “gold standard” screening tool relies on LC-MS/MS, which is not widespread; (4) the genetic analysis may be unavailable.

## 7. Therapy

The management of hypercalcemia due to *CYP24A1* variants should distinguish between an acute approach, aimed to reduce/normalize serum calcium concentration, and a maintenance approach, aimed to the maintenance of serum calcium concentrations stably within the reference range [6,8]. The management of HCINFI in the acute phase should not differ from the management of acute hypercalcemia due to any other cause [6]. Most patients diagnosed in the acute phase should be vigorously hydrated and eventually treated by a loop diuretic such as furosemide when the patient has been hydrated. Additional treatment employed in many reports includes bisphosphonates (pamidronate [43,44,46,60–64], risedronate [63], zoledronate [43]), denosumab [43], azoles (ketoconazole [26,31,34,65–67], fluconazole [68], itraconazole [63]), rifampine [69], glucocorticoids [43–45,61,62,67,68,70,71], calcitonin [44,46–48,62,64], and cinacalcet [63,72].

Each of the aforementioned medications acts on a different step of calcium homeostasis. Azoles reduce the synthesis of 1,25(OH)<sub>2</sub>D<sub>3</sub> by inhibiting the 1 $\alpha$ -hydroxylase enzyme (Fig. 69.2) and are effective in patients affected by *CYP24A1* loss-of-function mutations both in

**TABLE 69.1** Differential diagnosis of hypercalcemic disorders.

Disease	Serum calcium	$Cl_{Ca}/Cl_{Cr}$	PTH	PTHrP	25(OH) D <sub>3</sub>	1,25(OH) <sub>2</sub> D <sub>3</sub>	25(OH) D <sub>3</sub> : 24,25(OH) <sub>2</sub> D <sub>3</sub>	ACE	Genetics

the acute and in the chronic setting [34,68,73]. Rifampin, which activates an alternative catabolic pathway via the CYP3A4 enzyme (Fig. 69.2), thus catalyzing a nonspecific hydroxylation of  $1,25(\text{OH})_2\text{D}_3$  to the inactive metabolite,  $1,23,25(\text{OH})_3\text{D}_3$ , and the 4-hydroxylation of  $25(\text{OH})\text{D}_3$ , is effective in both the short- [69] and the long-term treatment [74]. The use of corticosteroid to reduce intestinal calcium absorption in patients with hypercalcemia related to *CYP24A1* mutations [65] has been discouraged because its therapeutic benefit requires a functioning CYP24A1 enzyme [75]. Nonetheless, corticosteroids have been widely used with good results. One patient underwent hemofiltration [70], and two patients underwent parathyroidectomy [63,72]. The latter patients had coexistence of vitamin D-dependent hypercalcemia and primary hyperparathyroidism: whether this was a causal association or *CYP24A1* mutations are associated with an increased risk of primary hyperparathyroidism remains to be elucidated.

A direct comparison between the efficacy of the various therapeutic strategies in the acute phase is not feasible because available data derived from scattered reports, with a substantial inhomogeneity in the reported hypocalcemic effects, and the lack of randomized controlled trials. Moreover, when considering patients who received a combination of different therapies, it was not possible to understand the actual contribution of each single medication in the overall therapeutic effect.

The chronic management of hypercalcemia in the setting of *CYP24A1* mutations is somehow much more troublesome. Many patients do not require an active pharmacologic treatment [25], and it is reasonable to advise a “behavioral approach”: refrain from exogenous vitamin D supplementation, implementation of a low-calcium diet, and avoid unprotected excessive sunlight exposure. Nonetheless both the strictness and the benefits of these approaches remain to be clarified [37]. For instance, the restriction of dietary calcium should be carefully monitored since it may induce defective bone mineralization and increased intestinal oxalate absorption with the subsequent risk of oxalate stone formation, so there are currently no specific cutoffs for a recommended daily calcium intake. In addition, a recent study has shown that in many cases the behavioral approach alone is not sufficient to induce the normalization of urinary calcium excretion [25,74]. For patients requiring long-term pharmacological management, azoles and rifampin were the medications more often proposed. The efficacy of the different proposed therapies should not only include the hypocalcemic effect both in the acute long-term phases, but also the control of hypercalciuria or the progression of nephrocalcinosis [6,25,74].

An important issue is the management of hypercalcemia during pregnancy, a condition where hypercalcemia may be severe form and most medications cannot be administered [25]. Because of the high chance of obstetric complications, patients should be carefully informed and counseled before planning a pregnancy. Vitamin D supplementation should be avoided since this strategy is as effective in avoiding symptomatic hypercalcemia in repeated pregnancies [71].

## 8. Conclusion

Although frequently undiagnosed, *CYP24A1* mutations can be easily encountered in the clinical practice. The current prevalence of *CYP24A1* pathogenic variants is still unknown, even though it is thought to be high, especially in the European population.

*CYP24A1* loss-of-function mutations are responsible for a highly variable phenotype, ranging from acute hypercalcemia arising in the early infancy with the classical manifestations (nausea, vomiting, dehydration, failure to thrive, up to death), to a much milder phenotype presenting more often in the adulthood with mild hypercalcemia with increased rate of nephrolithiasis. Particular attention should be paid to pregnancy, a condition accompanied by a physiologic modification of vitamin D metabolism, when severe hypercalcemia may occur.

Due to the high phenotypic variability, the possibility of *CYP24A1* mutations should not be suspected only in the limited setting of infantile acute hypercalcemia, but even in each setting of PTH-independent hypercalcemia. Once the diagnosis is suspected, it should be confirmed by studying vitamin D metabolism and by genetic analysis.

The medical approach depends on the entity of hypercalcemia, ranging from vigorous measures aimed at a prompt normalization of serum calcium concentrations, to behavioral measures and lifestyle modifications aimed at a chronic maintenance of normocalcemia.

## 9. Summary points

- Loss-of-function *CYP24A1* mutations are responsible for an increase of  $25(\text{OH})\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  concentrations, thus resulting in a form of vitamin D-dependent hypercalcemia.
- The clinical phenotype of patients with biallelic loss-of-function *CYP24A1* mutations varies from severe acute hypercalcemia, more often presenting in the early infancy, to mild hypercalcemia presenting in the adulthood.

- Carriers of *CYP24A1* monoallelic mutations often present with serum calcium concentrations in the upper part of the normal range and have an increased rate of nephrolithiasis.
- The available therapies include first-line measures for the management of acute hypercalcemia, as well as pharmacologic approaches that can be considered, if necessary, for the long-term control of hypercalcemia.

# Vitamin D and osteoporosis

*Peter R. Ebeling*

Department of Medicine, School of Clinical Sciences, Monash University, Clayton, VIC, Australia

## OBJECTIVES

- Explore the effects of season on bone and mineral metabolism, and the evidence for identifying an optimal serum 25(OH)D concentrations for musculoskeletal health.
- Review the evidence for effects of vitamin D alone or calcium and vitamin D on bone mineral density (BMD) and falls.
- Review the evidence for primary fracture prevention with vitamin D or calcium and vitamin D, including metaanalyses and studies of high annual or monthly doses, and to make clinical recommendations based on this evidence.
- Review data on safety relating to calcium and vitamin D, and the evidence for secondary fracture prevention with vitamin D or calcium and vitamin D.
- Review the evidence on the effects of active vitamin D analogs on fractures.
- Review recent evidence on large randomized controlled trials of vitamin D supplementation.
- Review the evidence of vitamin D on bone health from Mendelian randomization studies.

## 1. Introduction

There are powerful inherited contributions to osteoporosis with up to 75% of variance in bone phenotypes, such as bone mineral density (BMD), bone size, and geometry, attributable to genetic factors in

healthy individuals. Allelic variation in the vitamin D receptor (VDR) was the first nonstructural gene to be associated with osteoporosis. These data, in conjunction with the effects of the vitamin D system in bone homeostasis, suggested that this vitamin might have a strong role in osteoporosis treatment. This possibility is consistent with effects of the active vitamin D metabolites directly on osteoblasts to increase bone formation and mineralization and to reduce osteoclast recruitment and increase their activity, while at the same time acting on the osteoclast pathway to increase osteoclast recruitment. In large-scale epidemiological data, serum 25-hydroxyvitamin D (25(OH)D) levels are associated with bone density in both men and women. However, there is mixed evidence on the effectiveness of vitamin D supplementation for the prevention of bone loss and minimal trauma fractures in postmenopausal women and older men. This may be explained by vitamin D being a threshold nutrient, with a threshold in vitamin D status below which disease risk increases and vitamin supplementation is beneficial. In this regard, two recent randomized controlled trials (RCTs) have shown vitamin D supplementation increases bone mineral density in individuals with baseline serum 25(OH)D concentrations <30 nmol/L. There is also likely to be some benefit on primary fracture prevention for those with the highest background fracture risk including those patients who have deficient serum concentrations of 25(OH)D and institutionalized patients, but only when combined with calcium supplements. In women and men aged >50 years, the combination of vitamin D with calcium, but not vitamin D alone, has a modest effect in preventing fractures by 5%–30%, depending on fracture site and study. There is no evidence that vitamin D alone can

prevent fractures in community-dwelling, vitamin D–replete older adults, nor that the combination of calcium and vitamin D, or either alone, can prevent fractures in patients with preexisting minimal trauma fractures. The daily dose of vitamin D should be at least 800 IU (20 µg). There is evidence that daily doses of  $\geq 4000$  IU may be harmful for bone in postmenopausal women, but not in men. Larger monthly or annual doses are also not recommended as in two studies, large single either annual (500,000 IU) or monthly (60,000 IU) doses of vitamin D increased falls and, possibly, fractures in elderly men and women. Vitamin D, calcium, or the combination of both, are not effective in secondary fracture prevention. However, vitamin D supplementation is required in patients with suboptimal serum 25(OH)D concentrations ( $<20$  ng/mL,  $<50$  nmol/L) before antiosteoporosis treatment with bisphosphonates or other antiresorptive drugs, particularly intravenous zoledronic acid and subcutaneous denosumab, to help minimize the risk of hypocalcemia and to optimize the antifracture efficacy of antiresorptive drugs. Active vitamin D metabolites are not recommended for the treatment of osteoporosis.

## 2. Effects of vitamin D on the skeleton

Vitamin D deficiency states result in the failure of normal mineralization of bone. This presents in childhood as rickets and in the mature skeleton as osteomalacia (see Chapters 62 and 63). The consistent finding between these two states is inadequate mineralization of the formed matrix, such that the bones are softened and deformed. There has been considerable discussion as to whether this is entirely due to the major role of active vitamin D metabolites in stimulating gut calcium (and phosphorus) absorption or whether there are additional specific effects on bone. In the former concept, it is proposed that there is failure of the provision of adequate calcium and phosphorus that is required for mineralization to proceed. In the latter, it is proposed that there are additional roles of active vitamin D metabolites in regulation of both bone formation and bone resorption (see Chapters 21–23).

Parathyroid hormone (PTH), which rises in response to low serum calcium, stimulates renal production of 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) that in turn stimulates gut calcium absorption. When there is active absorption of intestinal calcium into the circulation, the rise in serum calcium decreases renal  $1\alpha$ -hydroxylase (the *CYP27B1* gene product) activity both directly and indirectly, through decreasing PTH and increasing fibroblast growth factor-23 levels (see Chapters 8 and 19). This classic negative feedback loop, which has been

well characterized, does not, however, address the direct effect of vitamin D on the skeleton.

The presence of the VDR in bone cells suggests direct effects on bone (see Chapter 23). These receptors are expressed in osteoblasts (see Chapter 22) and in immature cells of the osteoclast precursor lineage (see Chapter 21). It was proposed some time ago that the effect of the active vitamin D metabolites on osteoclasts was indirect via osteoblasts. The clearest potential to discriminate between these direct and indirect vitamin D effects on bone came through the VDR-knockout models [1–8]. In these, there was good evidence that the osteomalacic phenotype could be largely rescued by a high-calcium, high-lactose diet, which overcame the poor gut calcium absorption defect. However, these findings do not preclude other roles of vitamin D in modulating bone cell function. In these studies, a specific role is supported for the VDR in chondrocytes [9,10].

One set of findings that suggest a specific role of vitamin D in bone cells was the overexpression of the VDR in mature cells of osteoblastic lineage [11,12]. These studies reported increased bone mass in mice and stronger bones characterized by increased calcium content of the mineral phase. However, in other studies, VDR knockout was associated with increased osteogenic activity [7]. The diametric difference between these studies is yet to be determined. In relation to the specific VDR overexpression model, there were both in vivo and in vitro studies, demonstrating decreased osteoclastic activity. In the in vitro model, this effect appeared to be driven by the osteoblasts with higher intrinsic VDR levels [13].

Other preclinical models have explored the effects of vitamin D on osteoclastogenesis. Bone volume was positively associated with circulating 25(OH)D concentrations, while osteoclast surface levels were positively associated with receptor activator of nuclear factor- $\kappa$ B ligand (RANKL):osteoprotegerin (OPG) messenger RNA (mRNA) ratio, which were, in turn, higher in groups with lower serum 25(OH)D concentrations, but independent of serum  $1,25(\text{OH})_2\text{D}$  concentrations. Serum 25(OH)D concentrations  $<32$  ng/mL (or 80 nmol/L) resulted in osteopenia due to increased osteoclastogenesis, consistent with human data [14].

The skeleton also appears to be responsive to serum levels of the  $1,25(\text{OH})_2\text{D}$  precursor, 25(OH)D, in terms of bone mineralization [15]. Human osteoclast cultures incubated with 25(OH)D produce measurable quantities of  $1,25(\text{OH})_2\text{D}$ . The expression of osteoclast transcription factor, osteoclast marker genes, and an osteoblast coupling factor, ephrin-b2, is also increased in the presence of 25(OH)D in vitro. Levels of *CYP27B1* and nuclear factor of activated T cells-1 mRNA correlated during osteoclastogenesis and in a cohort of human bone samples. 25(OH)D dependently reduced the resorptive

capacity of osteoclasts, whereas, conversely, osteoclasts formed from VDR-null mouse splenocytes have increased resorptive activity. Thus, it is likely that 25(OH)D metabolism is an important intrinsic mechanism for optimizing osteoclast differentiation and reducing osteoclast activity.

In rodents, the major determinants of serum 25(OH)D are dietary vitamin D and calcium. Compared with animals fed a diet deficient in calcium, animals fed 0.1% calcium had higher renal *CYP27B1* mRNA expression and 12- to 18-fold increased levels of serum 1,25(OH)<sub>2</sub>D [16]. Thus, the reported effects of low-calcium diets on bone loss may be, in part, due to the adverse effects on 25(OH)D metabolism, leading to a reduction in active vitamin D. This potential interaction between dietary calcium and vitamin D metabolism has important implications, given the recent evidence for local synthesis of active vitamin D in bone tissue, and may explain why the combination of calcium and vitamin D is more effective than vitamin D alone in preventing fractures.

In this regard, in the mouse model overexpressing the VDR in both osteoblasts and osteocytes (OSVDR), there was inhibition of bone resorption and increased bone formation. When OSVDR mice were fed a vitamin D deficiency diet, they displayed an increased cortical and cancellous bone volume compared with wild-type mice, which remained higher during vitamin D depletion due to reduced osteoclast numbers and an increased bone formation rate [17]. These data suggest that increased VDR-mediated activity in osteoblasts and osteocytes may prevent bone loss due to vitamin D deficiency.

Overall, these findings suggest two distinct levels of function of the active vitamin D metabolites on bone: a general effect through changes in gut calcium absorption and a fine-tuning effect on the specific activity of the osteoblasts and osteoclasts in bone.

### 3. The role of vitamin D genetic factors in osteoporosis and possible interactions with vitamin D therapy

A variety of risk prediction models have examined family history and shown that a positive family history contributes to risk. Typically, this increased risk has odds ratios of 1.1–1.5. Family history of hip fracture is used in the FRAX fracture risk calculator. The recognition of heritability in osteoporosis led initially to studies of many candidate genes and more recently to large-scale, genome-wide studies. The initial demonstration of the relationship of the VDR to bone turnover and bone density [18,19] was followed by many candidate gene approaches [20–28]. Replication of these findings has been “variable” in different ethnicity and age

samples, even for the two most studied loci, the VDR and collagen Iα1 genes, which are possibly influenced by gene–environment interactions [22,24,28–34]. The gene discovery approach of genome-wide analysis of extreme phenotypes (mutations) in small families led to discovery of the low-density lipoprotein receptor–related protein-5 [35,36]. This work opened understanding of new and previously unsuspected bone anabolic pathways [37–40].

Large-scale, population-based, genome-wide association studies in osteoporosis and fracture risk [41–43] have identified not only, mainly, known bone-related genes but also some other potential genetic targets. The OPG, RANK and RANKL, sclerostin, and estrogen receptor genes were among those to be detected, but several other novel loci are yet to be investigated [42–44]. Another approach has been to perform genome-wide scans in subsamples of high- and low-bone-density individuals selected from normal populations [45].

The primary phenotype in most such studies has been lumbar spine and proximal femur BMD by dual-energy X-ray absorptiometry. This has been extended to a variety of geometric and mechanical parameters, including estimated femoral neck volumetric BMD, width, cross-sectional area, endosteal diameter, mean cortical thickness, cross-sectional moment of inertia, buckling ratio, and section modulus [46–50]. Rate of change of BMD and even fracture incidence have also been considered as phenotypes. Some studies have also reported a strong association between serum 25(OH)D levels and polymorphisms in the vitamin D-binding protein (DBP) gene as well as genes involved in vitamin D metabolism, particularly one of the 25-hydroxylase genes [51–53].

One of the major challenges has been the relatively limited reproducibility of associations between studies. However, this may relate to environmental differences and to ethnic differences in other gene variants. This possibility is supported by recent studies reporting interactions between the variants of the VDR, DBP, and calcium-sensing receptor genes in determining response to therapy including to vitamin D [54–56]. One study has provided new genetic data that might explain why there is considerable interindividual variability of serum 25(OH)D levels [57]. As only 25% of this variability is accounted for by season, latitude, or vitamin D intake, behavioral and genetic factors have been thought to contribute to this variability.

A large, multicenter, genome-wide association study of 15 cohorts in Europe, Canada, and the United States, comprising about 30,000 white people from European descent, found that polymorphisms at three different loci involved in vitamin D metabolism affect serum 25(OH)D levels and the risk of vitamin D deficiency and insufficiency. After accounting for age, sex, body

mass index, and season, polymorphisms in at least three, and perhaps four, loci influenced serum 25(OH)D levels. The first three genes below were identified in the discovery sample and confirmed in the replication sample, while the fourth candidate gene was identified in pooled analyses of the discovery and replication samples: (1) 4p12 polymorphisms near or within the *GC* gene, which encodes DBP, the main transporter of vitamin D metabolites in the blood; (2) 11q12 polymorphisms near *DHCR7/NADSYN1*, encoding the enzyme 7-dehydrocholesterol (7DHC) reductase, which converts 7DHC into cholesterol in the skin, thereby removing the substrate for production of vitamin D<sub>3</sub>; (3) 11p15 polymorphisms near *CYP2R1*, encoding an enzyme responsible for 25-hydroxylation of vitamin D in the liver; (4) *CYP24A1* encoding 24-hydroxylase, which initiates degradation of 25(OH)D and 1,25(OH)<sub>2</sub>D. Participants with a genotype score (combining the three main variants) in the top quartile had twice the risk of having vitamin D insufficiency (<50 or 75 nmol/L) than those in the lowest quartile. It was also associated with a 1.5-fold risk of severe vitamin D deficiency (<20 nmol/L). These findings are important, as they confirm that common genetic variants may contribute to the interindividual variability of serum 25(OH)D levels and may predispose to (or protect against) vitamin D deficiency and insufficiency. This study also raised new questions regarding genetic regulation of serum 25(OH)D: (1) Will the same genetic variants be found in other ethnic groups? (2) Will these genetic variants explain the high variability that is clinically apparent in response to either ultraviolet B (UVB) exposure or to vitamin D supplementation? (3) Are there other less common genetic variants that also affect serum 25(OH)D levels (see Section 12)?

In addition to the role of genetic variants in determining serum 25(OH)D, *VDR* genotypes have been included in a genetic risk score (GRS) for fracture based on 62 BMD-associated single-nucleotide polymorphisms [58]. Individuals with greater GRS had lower femoral neck BMD. In addition, each unit increase in GRS was associated with a hazard ratio (HR) of 1.20 for fracture, independent of age, prior fracture, and falls. This significant association between GRS and fracture was observed for vertebral and wrist fractures, but not for hip fracture. Thus, genetic profiling of BMD-associated genetic variants could improve the accuracy of fracture prediction.

#### 4. Seasonal variation in vitamin D status

Many studies have demonstrated seasonal variations in serum 25(OH)D with a decline during the winter months [59–65]. More importantly, studies from both

the northern and southern hemispheres have shown seasonal variations in serum 25(OH)D concentrations, accompanied by responsive changes in serum PTH concentrations, later increases in bone resorption markers and bone formation markers and decreases in BMD. In 43 German subjects followed for 1 year, bone turnover was significantly accelerated, and lumbar spine and femoral BMD declined by 0.3%–0.9% during the winter months. Supplementation with oral 500 mg calcium and 500 IU cholecalciferol per day for 1 year either reversed or abolished seasonal changes in calciotropic hormones and markers of bone turnover in the intervention group, while these changes remained in a control group. In the subjects receiving oral cholecalciferol and calcium, lumbar and femoral BMD increased significantly, whereas controls continued to lose bone [66].

Rates of hip fracture also vary annually, with a winter peak in both northern and southern hemispheres [67,68]. Inadequate vitamin D levels have been demonstrated in patients with osteoporosis [69], including hip fracture patients in many countries, although low levels may be influenced by the fracture itself [70–72]. It is also important to note that vitamin D deficiency increases with aging and that this contributes independently to secondary hyperparathyroidism [73].

In addition, serum androgen levels in men are associated with serum 25(OH)D concentrations, and both have a concordant annual periodicity being lowest in late winter [74], suggesting important, and as yet unidentified, links between the vitamin D and sex steroid axes. Similarly, in southeastern Australia (latitude 38–39°S), in 287 women drawn from an observational, cross-sectional, population-based study [75], annual periodicities of ultraviolet radiation, serum 25(OH)D, serum PTH, a bone resorption marker, serum C-telopeptide (CTx), BMD, falls, and fractures were measured. Cyclic variations in serum 25(OH)D lagged 1 month behind ultraviolet radiation, peaking in summer and dipping in winter. The periodicity of serum PTH was the inverse of serum 25(OH)D, with a phase shift delay of 1 month. Peak serum CTx lagged peak serum PTH by 1–2 months. In late winter, a greater proportion of falls resulted in fracture. Seasonal periodicity in 439 hip and 307 wrist fractures also followed a simple harmonic model, peaking 1.5–3 months after the trough in 25(OH)D. Thus, a fall in serum 25(OH)D in winter is accompanied by increases in serum PTH levels, bone resorption, and the proportion of falls resulting in fracture, and more hip and wrist fractures [75].

Only one English study did not show such a seasonal variation in bone turnover markers [76]. Season appears to be more important than latitude in determining serum 25(OH)D in many countries. However, in Australia, both season and latitude accounted for less than 20% of the variation in serum 25(OH)D levels,

highlighting the importance of behavioral and genetic factors, including sun avoidance [77]. Such seasonal declines in vitamin D metabolites and the associated increases in hip and wrist fracture rates make interventions with vitamin D a logical intervention.

### 5. Determining optimal serum 25-hydroxyvitamin D concentrations for musculoskeletal health

Previous attempts to define an optimal serum 25(OH)D for musculoskeletal health have used indirect measures such as the relationships between serum 25(OH)D and PTH concentrations in normal adult populations with a plateau of serum PTH above 31 ng/mL (78 nmol/L) [78]. A major role for active vitamin D metabolites is in stimulating gut calcium (and phosphorus) absorption. This effect may not be uniform across all age groups, and in humans, there is evidence of an age-related intestinal resistance to 1,25(OH)<sub>2</sub>D that may be secondary to reduced levels of intestinal VDR [79]. Despite an age-related increase in serum PTH and in serum 1,25(OH)<sub>2</sub>D concentration, intestinal VDR concentration decreased with age, whereas active calcium absorption did not change. These data are most consistent with impaired intestinal responsiveness to 1,25(OH)<sub>2</sub>D action. This gut defect could lead to compensatory increases in PTH secretion and 1,25(OH)<sub>2</sub>D<sub>3</sub> production, which maintain calcium absorption and serum calcium, but at the expense of increased bone loss. Serum 25(OH)D concentrations are also related to active calcium absorption [80], albeit not as strongly, and one study showed a plateau in active intestinal calcium absorption at serum 25(OH)D concentrations  $\geq 32$  ng/mL (80 nmol/L).

A randomized, double-blind, placebo-controlled clinical trial studied 230 postmenopausal women aged  $\leq 75$  years with baseline 25(OH)D levels of 35–68 nmol/mL and no osteoporosis, who were given placebo, 800 IU vitamin D<sub>3</sub> daily, or 50,000 IU vitamin D<sub>3</sub> every 2 weeks for 1 year. The high-dose vitamin D achieved and maintained 25(OH)D levels  $>75$  nmol/L and resulted in small (1%) increases in active calcium absorption. However, this effect did not translate into beneficial effects on BMD, muscle function, muscle mass, or falls [81].

Others have related serum 25(OH)D concentrations to fracture risk. In a nested, case-control study from the Women's Health Initiative, 400 hip fracture patients and 400 controls matched based on age, race, or ethnicity, and date of blood draw were followed for a median of 7.1 years to assess fractures. Lower serum 25(OH)D concentrations were associated with increased hip fracture risk (adjusted odds ratio [OR] for each

25 nmol/L decrease, 1.33). Women with the lowest 25(OH)D concentrations ( $\leq 47.5$  nmol/L) had a higher hip fracture risk than did those with the highest concentrations ( $\geq 70.7$  nmol/L) (adjusted OR, 1.71), and the risk increased statistically significantly across quartiles of serum 25(OH)D concentrations. Importantly, this association was, in part, mediated by increased bone resorption. Thus, serum 25(OH)D concentrations  $\leq 20$  ng/mL (50 nmol/L) are associated with a higher risk for hip fracture [82].

In another study of 1311 community-dwelling older Dutch men and women followed for 6 years, a low serum 25(OH)D level ( $<12$  ng/mL or 30 nmol/L) increased the risk of fracture in those individuals aged 65–75 years (HR = 3.1; 95% confidence interval (CI), 1.4–6.9), but not in the older group of individuals (75–89 years) [83].

The aforementioned inferences about optimal serum 25(OH)D levels are drawn from association studies. Stronger evidence relates to the effects of vitamin D supplementation on musculoskeletal endpoints, particularly in increases in BMD, a reduction in falls and fractures and the serum 25(OH)D threshold concentrations needed to achieve these outcomes. The antifracture efficacy of oral vitamin D supplementation in women and men  $\geq 65$  years old has been assessed in a metaanalysis of 12 double-blind randomized controlled trials (RCTs) for nonvertebral fractures ( $n = 42,279$ ) and 8 RCTs for hip fractures ( $n = 40,886$ ) [84]. The pooled relative risks (RRs) were 0.86 (95% CI, 0.77–0.96) and 0.91 (95% CI, 0.78–1.05) for the prevention of nonvertebral fractures or hip fractures, respectively. However, there was significant heterogeneity for both endpoints. Factors explaining the heterogeneity were the daily dose and achieved serum 25(OH)D concentrations. When examining the trials with a higher (482–770 IU/day) received dose (i.e., dose adjusted for adherence) of vitamin D, nonvertebral fractures were reduced by 20% and hip fractures by 18%, whereas doses  $<400$  IU/day did not show any effect.

Furthermore, vitamin D has been shown to improve muscle strength and performance and to reduce the risk of falling in community dwelling, as well as in the institutionalized elderly. A metaanalysis including eight double-blind RCTs ( $n = 2376$ ) demonstrated that falling was significantly reduced by 13% in vitamin D-supplemented individuals compared with those receiving either calcium or placebo. Again, a significant heterogeneity by daily dose and achieved 25(OH)D levels was observed. Higher doses of vitamin D supplements (700–1000 IU/day) reduced the relative risk of falls by 19% [85,86]. Collectively, this translates to an achieved serum 25(OH)D level of at least 24 ng/mL (60 nmol/L) for antifall efficacy and at least 30 ng/mL (or 75 nmol/L) for antifracture efficacy [87,88].

Thus, most clinicians would regard a target range for serum 25(OH)D between 20 and 30 ng/mL (50–75 nmol/L) as being required for optimal musculoskeletal health. However, an Institute of Medicine report recommended at least 20 ng/mL (50 nmol/L) [89], which does not take season into account. Australian guidelines recognize the importance of season and recommend a level of at least 20 ng/mL (50 nmol/L) at the end of winter and early spring [90].

## 6. Effects of vitamin D alone or calcium and vitamin D on bone mineral density and falls

A systematic review of 17 RCTs evaluated the effect of supplemental vitamin D<sub>2</sub> or D<sub>3</sub> on BMD, predominantly in populations of late menopausal women [91]. Most trials had small sample sizes, were 2–3 years in duration, and used vitamin D doses of ≤800 IU per day. In addition, most trials used vitamin D<sub>3</sub> and also included calcium ≥500 mg as a cointervention. Combined results of trials of vitamin D<sub>3</sub> plus calcium versus placebo were consistent with small positive effects on lumbar spine, femoral neck, and total body BMD. The Women's Health Initiative trial found a significant benefit of vitamin D<sub>3</sub> 400 IU plus 1000 mg of calcium on total hip BMD [92]. Although there were no effects on spine BMD, this large study had several potential cofounders including 30% of participants already taking a calcium supplement, 30% having a high dietary calcium intake (>1200 mg/day), 52% receiving current hormone replacement therapy

(HRT), and a large proportion of patients taking a bisphosphonate at study end, as well as poor adherence with calcium and vitamin D supplements.

However, in combined trials of vitamin D<sub>3</sub> plus calcium versus calcium, a significant increase in BMD was not observed, suggesting vitamin D<sub>3</sub> is of little benefit in calcium-replete postmenopausal women. Vitamin D<sub>3</sub> alone versus placebo did not show significant increases in BMD, except in one trial that noted an increase in femoral neck BMD [93]. Only a few previous trials reported the impact of baseline serum 25(OH)D concentrations on BMD, and in all these trials, a lower baseline serum 25(OH)D was not associated with a greater BMD increase. However, two recent large RCTs show that greater BMD increases are seen in individuals with baseline serum 25(OH)D concentrations <30 nmol/L. In a substudy of the Vitamin D Assessment (ViDA) study, Reid et al. [94] studied whether monthly high-dose (100,000 IU) vitamin D supplementation given for 2 years influenced BMD in 452 New Zealand adults (mean age 69 years) or in those with low baseline serum 25(OH)D concentrations. The baseline serum 25(OH)D concentration in the total trial population was 58 nmol/L, and there were no significant changes in BMD at the lumbar spine or total body, but a reduction of the loss of femoral neck and total hip BMD by 0.5%. In the subgroup with the poorest vitamin D status at baseline (<30 nmol/L), BMD at the lumbar spine and femoral neck remained unchanged, whereas a 2% loss was recorded in the placebo group (Fig. 70.1).

**FIGURE 70.1** Effect of monthly high-dose vitamin D on bone density in community-dwelling older adults: Substudy of a randomized controlled trial (ViDA-BMD) [94]. Reproduced from Ref. [94], with permission from Wiley.

A second study recruited 305 postmenopausal women in late winter and randomized them to receive placebo, vitamin D 400 IU/day, or vitamin D 1000 IU/day over 1 year. Although bone loss from the hip was reduced by vitamin D 1000 IU/day only, there was no significant treatment effect of either dose at the spine [95]. However, in the trial participants with a baseline 25(OH)D concentration  $\leq 30$  nmol/L, significant treatment effects were seen at both the spine and hip, with no significant effects on BMD in those with baseline 25(OH)D concentrations above this level [95]. Similar findings were seen in the largest RCT, VITAL, in which there was no significant treatment effect of daily 2000 IU vitamin D on BMD or bone structure in the overall study. However, among participants with baseline-free vitamin D levels below the median ( $<14.2$  pmol/L), there was a slight increase in spine BMD (0.75% vs. 0%;  $P = .043$ ) and less bone loss from the total hip ( $-0.42\%$  vs.  $-0.98\%$ ;  $P = .044$ ) with vitamin D<sub>3</sub> treatment [96].

The daily dose of vitamin D should be at least 800 IU. There is evidence that daily doses  $\geq 4000$  IU are harmful to bone in females, but not in males. A 3-year randomized, double-blind trial investigated the effects of high-dose daily vitamin D supplementation on bone density and strength in 311 postmenopausal women and older men. Vitamin D supplementation with 4000 IU or 10,000 IU, compared with 400 IU daily, resulted in greater losses of total tibial volumetric BMD, measured by high-resolution peripheral quantitative computerized tomography (HR-pQCT) over 3 years in healthy vitamin D-sufficient females, but not males with similar trends being seen at the radius. There were no differential effects on bone strength [97].

A prior metaanalysis examined effects of calcium or calcium combined with vitamin D on BMD and fractures in men and women aged  $>50$  years [98]. Of the 23 trials ( $n = 41,419$ ) reporting BMD as an outcome, calcium and calcium in combination with vitamin D were associated with a reduced bone loss of 0.54% at the hip, and 1.19% at the spine. A positive treatment effect on BMD was evident in most studies; however, the treatment effect of vitamin D alone was not assessed.

Calcium and vitamin D supplementation during winter results in increases in spinal and femoral neck BMD, compared with decreases in those older men and women not receiving supplements [66]. One trial examined the effect of the combination of calcium and vitamin D on bone structure and bone turnover compared with calcium alone [99]. Three hundred and two elderly women with baseline serum 25(OH)D concentrations  $<24$  ng/mL (60 nmol/L) participated in a 1-year randomized, double-blind, placebo-controlled trial of 1000 mg calcium per day with either 1000 IU ergocalciferol (vitamin D<sub>2</sub>) or identical placebo. Baseline

calcium intake was 1100 mg/day, and serum 25(OH)D was 18 ng/mL (44 nmol/L); this increased only in the vitamin D group to 24 ng/mL (60 nmol/L) after 1 year. Total hip and total body BMD increased significantly, and procollagen type I intact N-terminal propeptide (P1NP) decreased by  $\sim 4\%$  during the study, with no difference between the treatment groups. In addition, there was no effect on active fractional intestinal calcium absorption, which fell equally in both groups by 15%–17%. Thus, ergocalciferol (vitamin D<sub>2</sub>) 1000 IU for 1 year had no beneficial effects on bone structure, bone formation markers, or intestinal calcium absorption over an additional 1000 mg of calcium.

In the same cohort, falls risk was measured every 6 months. Ergocalciferol (vitamin D<sub>2</sub>) 1000 IU combined with calcium reduced the risk of having at least one fall over 1 year by 39% compared with calcium supplementation alone [100]. When those who fell were grouped by either the season of first fall or the number of falls, ergocalciferol treatment reduced the risk of having the first fall in winter and spring (ergocalciferol group, 25.2%; control group, 35.8%; OR, 0.55), but not in summer and autumn, and reduced the risk of having one fall by 50%, but not the risk of multiple falls. Thus, patients with a history of falling and vitamin D insufficiency benefited from vitamin D supplementation in addition to calcium, which was associated with an overall 19% reduction in the relative risk of falling, mostly in winter. However, a post hoc analysis of a large RCT of 5108 individuals treated with 100,000 IU vitamin per month versus placebo (ViDA study) for 2.5–4.2 years showed no difference in falls in this healthy, ambulatory, adult population [101]. In a double-blind, placebo-controlled RCT (VITAL), 25,871 adults (mean age, 67.1 years) were randomly assigned to cholecalciferol (2000 IU/day) and/or omega-3 fatty acids (1 g/day) or respective placebos in a  $2 \times 2$  factorial design [102]. The numbers of participants with  $\geq 2$  falls were similar between active and placebo groups. Over 5 years, there were no differences in the proportion having  $\geq 2$  falls, or falls resulting in a doctor visit, or a hospital visit between groups. The results also did not differ between those with baseline serum 25(OH)D concentrations  $<$  or  $\geq 50$  nmol/L, although the proportion of the study population with serum vitamin D  $< 50$  nmol/L was low (14.8%). Other studies show either no effect or an increased risk of falls with vitamin D. A placebo-controlled RCT of community-dwelling Finnish women aged 70–80 years with a baseline 25(OH)D concentration of 32 nmol/L showed vitamin D (800 IU/day) with or without exercise showed no effect of vitamin D on the falls rate [103]. A smaller 1-year dose-ranging study in postmenopausal women selected for vitamin D deficiency indicated in a secondary analysis a U-shaped curve of effects of the seven combined vitamin D doses on fall

risk, compared with the placebo group [104]. In older community-dwelling adults aged  $\geq 70$  years, annual bolus doses of 500,000 IU and monthly doses of 60,000 IU have been shown in prior studies to increase falls in community-dwelling older adults (see the following).

A 5-year randomized, controlled, double-blind trial of 120 community-dwelling women aged 70–80 years compared 1200 mg/day calcium with placebo vitamin D (Ca group) or with 1000 IU/day ergocalciferol (vitamin D<sub>2</sub>) (CaD group), or double placebo (control) [105]. Hip BMD was preserved in both intervention groups, but not in controls at year 1 and maintained in the CaD group only over the long term at years 3 and 5. At year 1, compared with controls, the Ca and CaD groups had lower bone turnover markers. At 5 years, the suppression of bone formation and bone resorption markers was maintained only in the CaD group, and this decrease was also associated with reductions in PTH at 3 and 5 years compared with controls. Thus, although the combination of calcium with vitamin D had no additional effect over calcium alone in the short term (at 1 year), continuing skeletal benefits appear to be greater with this combination over the long term (up to 5 years).

Another study examined effects of calcium and vitamin D–fortified milk (1000 mg of calcium plus 800 IU of vitamin D<sub>3</sub>) compared with normal diet over 24 months in older men [106]. After 2 years, the mean percent decrease in BMD was 0.9%–1.6% less in the milk supplementation compared with control group at the femoral neck, total hip, and radius. There was a greater increase in lumbar spine BMD in the milk supplementation group after 12 and 18 months, but not after 2 years. Serum 25(OH)D increased and PTH decreased in the milk supplementation relative to control group after both years of the study. After a further 18 months of follow-up, during which neither group received calcium- and vitamin D<sub>3</sub>–fortified milk, the net beneficial effects of fortified milk on femoral neck and radius BMD at the end of the intervention were sustained [107]. However, there were no lasting benefits at the lumbar spine, suggesting the possibility of sustained skeletal benefits on cortical bone after withdrawal.

## 6.1 Conclusion

Treatment with the combination of calcium and vitamin D prevents bone loss and results in small increases in BMD at most sites. For long-term maintenance of BMD up to 5 years, the combination of calcium and vitamin D appears to be better than calcium alone. These skeletal benefits of calcium and vitamin D may be maintained at some, but not all, skeletal sites after withdrawal. However, the data also suggest that vitamin D

alone is effective in maintaining or increasing BMD over 1–2 years in individuals with a serum 25(OH)D concentration  $< 30$  nmol/L. There is evidence that daily vitamin D doses of  $\geq 4000$  IU are harmful for bone in postmenopausal women. The addition of vitamin D to calcium is also likely to reduce the risk of falling, particularly in winter, in patients with a history of falling and vitamin D insufficiency. This may result in a reduction of falls-related fractures. This has not been seen with vitamin D alone and higher bolus doses of vitamin D, which appear to increase falls in older individuals.

## 7. Primary fracture prevention with vitamin D or calcium and vitamin D

Primary fracture prevention is the most important potential role for vitamin D supplementation. However, until recently, most studies have been performed using a combination of calcium and vitamin D supplementation rather than vitamin D alone. The quality of many studies has also been reduced first by poor long-term compliance with study medications, and rates have mostly ranged from 55% to 75%, and second by a high degree of variability of dosing regimens.

### 7.1 Effect of vitamin D alone on fractures

The study showing the most benefit of vitamin D supplementation alone on fracture reductions was by Trivedi et al. [108]. They studied 2037 men and 649 women aged 65–85 years, predominantly doctors, living in the general community in a randomized, double-blind, controlled trial of 100,000 IU oral vitamin D<sub>3</sub> (cholecalciferol) or matching placebo every 4 months over 5 years. After 5 years, 268 men and women had incident fractures, of whom 147 had fractures in common osteoporotic sites (hip, wrist or forearm, or vertebrae). Relative risks in the vitamin D group compared with the placebo group were 0.78 for any fracture (Fig. 70.2) and 0.67 for first hip, wrist or forearm, or vertebral fracture. Four hundred and seventy-one participants died; however, the relative risk for total mortality in the vitamin D group compared with the placebo group was not significantly reduced (RR = 0.88).

Metaanalyses, however, show no overall effect of vitamin D alone on fracture risk. A Cochrane review of 53 RCTs in postmenopausal women or men over 65 years compared vitamin D supplements with placebo or no intervention or calcium supplements [109]. Medication regimens varied from vitamin D<sub>3</sub> 700–800 IU daily. Results from 11 trials (27,693 participants) showed no significant reduction in incidence of new hip fracture (RR, 1.12; 95% CI, 0.98–1.29) and nonvertebral fractures

**FIGURE 70.2** Cumulative probability of any first fracture with 100,000 IU cholecalciferol every 4 months versus placebo over 5 years;  $P = .04$  [108]. Reproduced from Ref. [108], with permission from BMJ publishing group.

(RR, 1.05; 95% CI, 0.96–1.14) for vitamin D alone compared with placebo or no intervention. Four trials with 3021 participants compared vitamin D with calcium. There was no evidence of a statistically significant difference between vitamin D alone and calcium in the prevention of hip fracture (RR, 0.90; 95% CI, 0.61–1.32) or nonvertebral fractures (RR, 1.10; 95% CI, 0.91–1.33). There was evidence that vitamin D alone was less effective than calcium for the prevention of vertebral fracture (RR, 2.21; 95% CI, 1.08–4.53). Thus, there is no evidence for the effectiveness of vitamin D alone for prevention of fractures.

A good-quality systematic review (9 RCTs,  $n = 53,260$ ) investigated the need for calcium supplementation (500–1200 mg daily) in postmenopausal women and men receiving vitamin D (cholecalciferol 700–800 IU daily [6 RCTs] or 400 IU daily [3 RCTs]) for prevention of fractures [110]. Mean therapy duration was 20–84 months. Pooled results showed vitamin D alone was not associated with a reduction in risk of hip fracture (RR, 1.10; 95% CI, 0.89–1.36;  $P = .38$ ) or a reduction in risk of nonvertebral fractures (RR, 0.98; 95% CI, 0.83–1.16;  $P = .79$ ) compared with placebo. An indirect comparison of trials investigating vitamin D with calcium compared with those investigating vitamin D alone showed an RR of 0.75 (95% CI, 0.58–0.96;  $P = .02$ ) for hip fracture.

Another metaanalysis addressed the effect of vitamin D supplementation on all fractures in postmenopausal women and men aged 50 years or older [92]. The pooled results for all fractures included 10 double-blind RCTs and 3 open study–design trials ( $n = 58,712$ ) and did not show a significant reduction of fractures with vitamin D alone (pooled odds ratio, 0.90; 95% CI, 0.81–1.02). In this report, the benefit of vitamin D depended on additional calcium and was also primarily seen in institutionalized individuals.

Such negative results might be explained by heterogeneity between studies in doses of vitamin D. In a further metaanalysis of 12 double-blind RCTs among individuals aged 65 years or older, the antifracture efficacy of supplemental vitamin D increased significantly with either a higher received dose or a higher achieved 25(OH)D level for any nonvertebral fractures and for hip fractures [84]. No fracture reduction was observed for a received daily dose of  $\leq 400$  IU, whereas a higher received daily dose of 482–770 IU of supplemental vitamin D reduced nonvertebral fractures by 20% and hip fractures by 18%. Subgroup analyses for the prevention of nonvertebral fractures with the higher received dose suggested possibly better fracture reduction with cholecalciferol compared with ergocalciferol, whereas additional calcium did not further improve antifracture efficacy. Nonvertebral fracture reduction with the higher received dose was significant among all subgroups by age and dwelling, including younger individuals aged 65–74 years and those living in the community.

Using individual patient data from seven major randomized trials of vitamin D with calcium or vitamin D alone, yielding a total of 68,517 participants with a mean age of 70 years (14.7% men), the results indicated that vitamin D given alone in daily doses of 10–20  $\mu\text{g}$  (400–800 IU) was not effective in preventing fractures [111]. However, trials using vitamin D with calcium showed a reduced overall risk of fracture (HR, 0.92; 95% CI, 0.86–0.99;  $P = .025$ ) and hip fracture (all studies: 0.84; 0.70–1.01,  $P = .07$ ; studies using 10  $\mu\text{g}$  (400 IU) of vitamin D given with calcium: 0.74; 0.60–0.91,  $P = .005$ ). No interaction was found between fracture history and treatment response, nor was there any interaction with age, sex, or HRT.

Three recent large trials (DO-HEALTH, ViDA, VITAL) have published data on incident fracture in older community-dwelling healthy adults treated with vitamin D or placebo. Data are also being analyzed in a third trial, which compared 60,000 IU vitamin D per month with placebo over 5 years (D-Health).

The 3-year DO-HEALTH study examined whether 2000 IU daily vitamin D, omega-3 fatty acids, and a strength-training exercise program, alone or in combination, reduced nonvertebral fractures among 2157 adults aged  $\geq 70$  years (mean age 74.9 years) without previous major health events. The mean baseline serum 25(OH)D concentration was 56 nmol/L (22.4 ng/mL) and increased to 94 nmol/L (37.6 ng/mL). There was no effect of any of the interventions on nonvertebral fractures [112].

The ViDA study compared monthly vitamin D 100,000 IU per month versus placebo for 2.5–4.2 years in 5108 healthy, ambulatory, adults and showed no difference in incident fractures (HR, 1.19; 95% CI, 0.94–1.50,  $P = .15$ ) [101] (Fig. 70.3). In a double-blind,

**FIGURE 70.3** Cox proportional hazards model of nonvertebral fractures recorded during follow-up with 100,000 IU cholecalciferol per month and placebo. Lines depict the proportion of participants having a fracture during follow-up, and shading represents the 95% CI. HR, hazard ratio [101]. Reproduced from Ref. [101], with permission from Lancet publishing group.

placebo-controlled RCT (VITAL), 25,871 adults were randomly assigned to cholecalciferol (2000 IU/day), and/or omega-3 fatty acids (1 g/day) or respective placebos in a  $2 \times 2$  factorial design [113] for 5 years. The mean baseline 25(OH)D level (16,757 participants) was  $30.7 \pm 10.0$  ng/mL (77 nmol/L). At baseline, 2.4% had 25(OH)D levels <12 ng/mL (30 nmol/L) and 12.9% had levels <20 ng/mL (50 nmol/L). The numbers of participants with incident total, nonvertebral, and hip fractures were similar between active and placebo groups (Fig. 70.4). There was also no effect of vitamin D on BMD or bone structure; however, in participants with baseline free 25(OH)D levels below the median, supplemental vitamin D<sub>3</sub> resulted in slight increases in spine and total hip BMD. From these two studies, vitamin D<sub>3</sub> supplementation did not result in a significantly lower risk of fractures than placebo among generally healthy midlife and older adults not selected for vitamin D deficiency, low bone mass, or osteoporosis. However, there was limited study power to examine effects of vitamin D on fractures in patients with vitamin D deficiency because of the low numbers of fractures in participants with vitamin D deficiency at baseline.

### 7.1.1 Conclusion

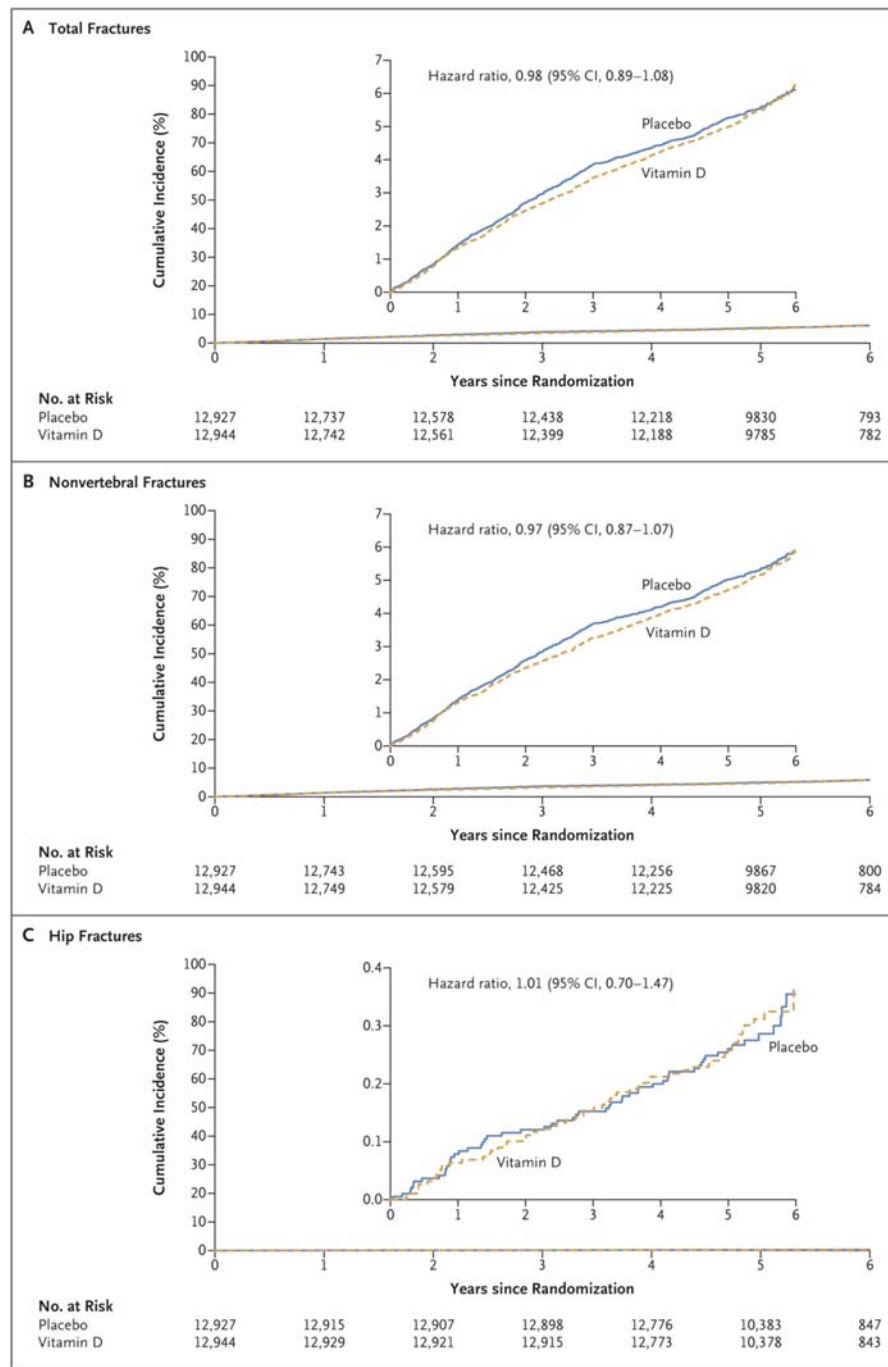

Overall evidence from several metaanalyses shows no effect of vitamin D alone on fracture risk. Although the effects of vitamin D on fracture risk may be masked both by heterogeneity of the received daily doses between studies, and the low numbers of included participants with vitamin D deficiency at baseline, the

evidence for vitamin D reducing the risk of nonvertebral and hip fractures is most compelling with the use of additional calcium in institutionalized individuals.

## 7.2 Single high annual or monthly doses of vitamin D

The first study investigating single large annual doses of vitamin D utilized an annual intramuscular injection of 150,000–300,000 IU vitamin D<sub>2</sub> (ergocalciferol) in 479 Finnish men and women aged >85 years, who were living in their own home and 320 subjects aged 75–84 years living in a home for aged people [114]. Although treatment allocation was not adequately randomized or blinded, the group of subjects administered intramuscular vitamin D had a significantly lower rate of all fractures. This was particularly marked for fractures of the upper limb but was not apparent for lower limb sites.

The second study was a randomized, double-blind, placebo-controlled trial of 300,000 IU intramuscular vitamin D<sub>2</sub> (ergocalciferol) injection or matching placebo every autumn over 3 years. Nine thousand four hundred and forty people (4354 men and 5086 women) aged  $\geq 75$  years were recruited from general practices in England [115]. Five hundred and eighty-five subjects had incident nonspine fractures (hip 110, wrist 116, ankle 37). HRs for fracture in the vitamin D group were 1.09 (95% CI, 0.93–1.28) for any first fracture, 1.49 (95% CI, 1.02–2.18) for hip, and 1.22 (95% CI, 0.85–1.76) for wrist. There was no effect on falls:

**FIGURE 70.4** Cumulative incident total, nonvertebral, and hip fractures with 2000 IU vitamin D daily and placebo [113]. Reproduced from Ref. [113], with permission from New England Journal of Medicine.

HR, 0.98 (0.93–1.04). When the analyses were confined to fractures at the wrist, hip, or both sites, fracture incidence tended to be higher in the vitamin D–treated arm when compared with placebo. However, these differences were not statistically significant. There was, however, a significant interaction between sex and treatment group on the risk of any nonvertebral fracture, such that a detrimental effect of vitamin D was seen among

women, but not among men ( $P < .03$ ). This implies annual intramuscular vitamin D<sub>2</sub> injections may increase the risk of nonvertebral fractures in women.

These data were confirmed in a double-blind, RCT of annual doses of oral cholecalciferol 500,000 IU, given in autumn or winter, versus placebo performed by Sanders et al. [116]. Two thousand two hundred and fifty-six community-dwelling women, aged  $\geq 70$  years, were

randomly assigned to receive oral cholecalciferol or placebo each autumn to winter for 3–5 years. Fractures were radiologically confirmed. Women in the cholecalciferol (vitamin D) group had 171 fractures versus 135 in the placebo group; the fall rate was 83.4 per 100 person-years in the vitamin D group, and 72.7 per 100 person-years in the placebo group (incidence rate ratio [IRR], 1.15,  $P = .03$ ). The IRR for fracture in the vitamin D group was 1.26 (95% CI; 1.00–1.59;  $P = .047$ ) versus the placebo group (rates per 100 person-years, 4.9 vitamin D vs. 3.9 placebo) (Fig. 70.5). A temporal pattern was observed in a post hoc analysis of falls. The IRR for falling in the vitamin D group versus the placebo group was 1.31 in the first 3 months after dosing and 1.13 during the following 9 months (test for homogeneity;  $P = .02$ ). Although not significant, the IRR for fractures was also increased in the vitamin D group versus the placebo group in the first 3 months compared with the following 9 months after dosing (RR, 1.53 vs. 1.18). The median baseline serum 25(OH)D was 49 nmol/L in this community-based study. In the vitamin D group, serum 25(OH)D concentrations increased at 1 month after dosing to  $\sim 120$  nmol/L and were  $\sim 90$  nmol/L at 3 months. The cause of the increased rate of falls or fractures after dosing is unknown but might relate to rapid fluxes in vitamin D metabolites or vitamin D–regulated genes or, perhaps, even to increased levels of physical activity.

A recent double-blind, randomized study has also raised concern about the safety of high monthly doses of vitamin D in older individuals [117]. Two hundred men and women with a prior fall were randomized to three monthly doses of vitamin D (24,000 IU vitamin D<sub>3</sub>, 60,000 vitamin D<sub>3</sub> and 24,000 vitamin D<sub>3</sub>, and

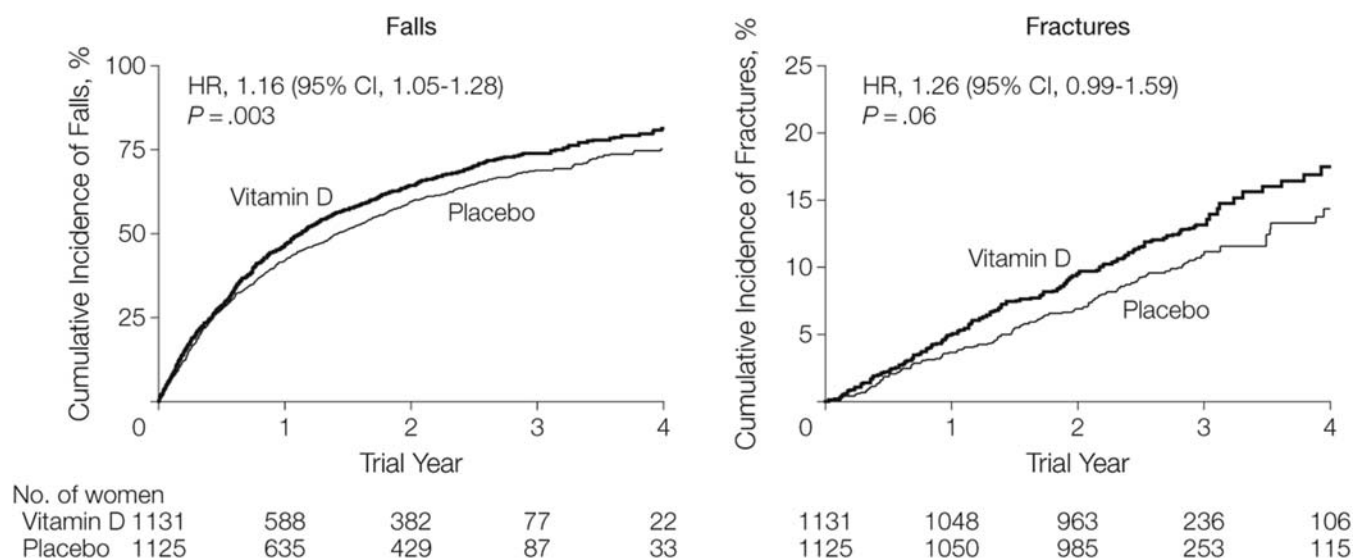

300  $\mu$ g calcidiol). Over 12 months of follow-up, there was a higher incidence of falls in the 60,000 IU vitamin D<sub>3</sub> and 24,000 vitamin D<sub>3</sub> and 300  $\mu$ g calcidiol groups, of 66.9% and 66.1%, respectively, versus 47.9% in the 24,000 IU group ( $P = .048$ ).

### 7.2.1 Conclusion

High annual or monthly doses of vitamin D are not recommended either to treat vitamin D deficiency or to prevent fractures in older women and men. In addition, the safety of high-dose vitamin D supplementation warrants further study, as the levels of 25(OH)D seen in these studies ( $\geq 48$  ng/mL or 120 nmol/L) may have had detrimental effects on falls and fractures in older men and women. In this regard, studies using either monthly doses of 50,000 IU cholecalciferol [118] or a loading dose of 10 daily doses of 50,000 IU cholecalciferol [119] achieved more modest increases in serum 25(OH)D to just above the optimal target range (75 nmol/L) at 3 months.

## 7.3 Primary fracture prevention with calcium and vitamin D

The pivotal study from which many metaanalyses on the effects of calcium and vitamin D on fractures derive their strength was performed in 3270 ambulatory elderly women (mean age 84 years) residing in institutional care (nursing homes or apartments) [120]. Supplementation with 1.2 g calcium and 800 IU cholecalciferol reduced hip fractures and nonvertebral fractures by 43% and 32%, respectively, and resulted in increases in hip BMD over 18 months (Fig. 70.5). The

**FIGURE 70.5** Increase in falls and fractures after an annual dose of 500,000 IU cholecalciferol [116]. CI, confidence interval; HR, hazard ratio. Reprinted from Ref. [116], with permission from the American Medical Association.

mean baseline serum 25(OH)D concentration was 16 ng/mL (40 nmol/L), meaning most women were vitamin D insufficient or deficient. The number needed to treat (NNT) to prevent a hip or nonvertebral fracture was 41 and 29, respectively. These data were confirmed in a later study performed by the same authors [121]. One study also showed calcium and vitamin D reduce fractures in community-dwelling healthy men and women. In 176 men and 213 women with a mean age of 70–72 years and having mean calcium intakes of 673–798 mg per day, 500 mg calcium and 700 IU cholecalciferol reduced nonvertebral fractures by 50% over 3 years and resulted in increases in hip, spine, and total body BMD [122]. The NNT to prevent a nonvertebral fracture was 15.

The largest study of calcium and vitamin D used daily doses of cholecalciferol (400 IU) that would now be considered suboptimal, and the mean baseline calcium intake in this study was also high (1150 mg/day) [92]. Thirty-six thousand two hundred and eighty-two postmenopausal women, aged 50–79 years, were randomly assigned to receive 1000 mg calcium with 400 IU cholecalciferol per day, or placebo. Participants receiving calcium plus vitamin D supplementation had a nonsignificant decrease in hip fracture risk (HR, 0.88; 95% CI, 0.72–1.08), HR of 0.90 for clinical spine fracture (0.74–1.10), and HR of 0.96 for total fractures (0.91–1.02). The risk of renal calculi increased with calcium plus vitamin D (HR, 1.17; 1.02–1.34). Censoring data from women when they ceased to adhere to the study medication indicated a reduction in hip fracture risk by 29% (HR, 0.71; 0.52–0.97).

Another study of 3432 community-dwelling northern Finnish women aged 65–71 years assessed incident fractures in women randomly assigned to receive 1000 mg calcium with 800 IU of cholecalciferol per day or placebo over 3 years [123]. The risk of any fracture decreased in the vitamin D and calcium group by 17% (95% CI, 0.61–1.12), and the risk of any nonvertebral fracture decreased by 13% (0.63–1.19). The risk of distal forearm fractures decreased by 30% (0.41–1.20), and the risk of any upper extremity fractures decreased by 25% (0.49–1.16), whereas the risk of lower-extremity fractures did not change. However, none of these effects reached statistical significance. This study provides further evidence that vitamin D and calcium supplementation does not prevent fractures in older community-dwelling postmenopausal women.

## 8. Metaanalyses

Metaanalyses indicate mixed evidence for the impact of oral calcium and vitamin D supplementation on reduction of fractures outside institutionalized settings.

One good-quality systematic review (29 studies, 63,867 individuals, 92% female) reported on the effect of calcium supplementation (alone or in combination with vitamin D) in doses of 1000–1200 mg in adults aged over 50 years [98]. Overall, calcium supplementation was associated with a 12% reduction in risk of any fracture (RR, 0.88; 95% CI, 0.83–0.95), with similar reduction in risk of fractures in trials using calcium supplements alone (10% risk reduction) and those where calcium was administered in combination with vitamin D (13% risk reduction). The estimated NNT to prevent one fracture over 3.5 years was 63 in the overall population. For individuals who were elderly, lived in institutions, had a low body weight, had a low calcium intake (less than 700 mg per day), or were at a higher baseline risk of fracture, the NNT to prevent one fracture over 3.5 years was 30. The fracture risk reduction was significantly greater (24%) in trials in which the compliance rate was high ( $P < 0.0001$ ). The treatment effect was better with daily calcium doses  $\geq 1200$  mg than with doses  $< 1200$  mg (0.80 vs. 0.94;  $P = 0.006$ ), and with daily vitamin D doses of  $\geq 800$  IU than with doses  $< 800$  IU (0.84 vs. 0.87;  $P = 0.03$ ). People with low serum 25(OH)D concentrations ( $< 25$  nmol/L) had a greater risk reduction compared with those whose serum 25(OH)D was normal (RR, 0.86 vs. 0.94); however, this result was not significant ( $P = .06$ ).

A good-quality systematic review (9 RCTs,  $n = 53,260$ ) investigated the need for calcium supplementation 500–1200 mg per day in postmenopausal women and men receiving vitamin D [either cholecalciferol 700–800 IU per day (6 RCTs) or 400 IU daily (3 RCTs)] for prevention of fractures [107]. Mean therapy duration was 20–84 months. Results (6 RCT,  $n = 45,509$ ) of vitamin D in conjunction with calcium supplements compared with placebo or no treatment showed a significant reduction in risk of both hip fracture (RR, 0.82; 95% CI, 0.71–0.94) and nonvertebral fracture (0.88; 0.78–0.99). The NNT to prevent one hip fracture over 24–84 months was 276, and NNT to prevent one nonvertebral fracture was 72. An indirect comparison of trials investigating vitamin D with calcium compared with those investigating vitamin D alone showed a significant risk reduction in hip fracture (RR, 0.75; 0.58–0.96).

A Cochrane review of 53 RCTs in postmenopausal women or men over 65 years compared calcium and vitamin D supplements to placebo, or no intervention [109]. Medication regimens varied from calcium 1000 to 1200 mg and vitamin D<sub>3</sub> 700 to 800 IU daily. Results from nine trials (49,853 participants) showed high quality evidence that vitamin D plus calcium results in a small reduction in hip fracture risk (RR, 0.84; 95% CI, 0.74–0.96;  $P = 0.01$ ). In low-risk populations (residents in the community), this equates to one fewer hip fracture

per 1000 older adults per year. In high-risk populations (institutionalized elderly), this equates to nine fewer hip fractures per 1000 older adults per year. There is also high-quality evidence from eight trials with 10,380 participants that vitamin D plus calcium is associated with a statistically significant reduction in incidence of new nonvertebral fractures (RR, 0.86; 95% CI, 0.78–0.96). However, there is only moderate quality evidence of an absence of a statistically significant preventive effect on clinical vertebral fractures. There is high-quality evidence that vitamin D plus calcium reduces the risk of any type of fracture (10 trials, 49,976 participants; RR, 0.95; 95% CI, 0.90–0.99).

A metaanalysis from the National Osteoporosis Foundation included eight studies with 30,970 participants who met criteria for inclusion in the primary analysis, with 195 hip fractures and 2231 total fractures [124]. It showed vitamin D and calcium supplementation

produced a statistically significant 15% reduced risk of total fractures (RR, 0.85; 95% CI, 0.73–0.98) (Fig. 70.6) and a 30% reduced risk of hip fractures (RR, 0.70; 95% CI, 0.56–0.87). A limitation was that this study utilized data from subgroup analysis of the Women's Health Initiative.

An alternative analysis of these data using a Bayesian approach found that the decrease in fracture risk was less certain, with an overall 13% reduction (RR, 0.87; 95% credible interval, 0.68–1.02) [125]. However, the heterogeneity between studies could be partially explained by differences in background risk between studies (Fig. 70.7). For example, in patients with a moderate background annual risk for fracture, say 50 per 1000 older adults, only 84 individuals need to be treated with vitamin D and calcium to prevent one fracture, whereas that number would be much higher for patients with a low background risk. This implies difficulty in

**FIGURE 70.6** Calcium plus vitamin D supplementation versus placebo and total fracture. CI, confidence interval; SSRE, summary relative risk estimate. Reproduced from Ref. [124], with permission from Springer.

**FIGURE 70.7** Relationship between effect size (log relative risk) and background risk of fracture [125]. Reproduced from Ref. [125], with permission from Springer.

making recommendations for reducing fractures with vitamin D and calcium at a population level.

A further metaanalysis of 33 randomized trials comparing supplements with placebo or no treatment involving 51,145 community-dwelling adults aged >50 years found no significant associations between calcium, vitamin D, or combined calcium and vitamin D supplements and the incidence of hip, nonvertebral, vertebral, or total fractures [126]. However, the Chapuy studies [120,121] of calcium and vitamin D were excluded, while the large RECORD trial of secondary fracture prevention (see the following) was included, limiting the inferences drawn from this metaanalysis.

A systematic umbrella review of metaanalyses of controlled trials examined 13 systematic reviews/metaanalyses (SR/MAs) on vitamin D and calcium (Ca/D) and 19 SR/MAs on vitamin D alone, compared with placebo/control [127]. Only 2 out of 10 SRs/MAs on Ca/D were of moderate quality. The combination of calcium and vitamin D reduced the risk of hip fractures in 8 of 12 SRs/MAs relative risk ([RR] 0.61–0.84), and any fractures in 7 of 11 SR/MAs (RR 0.74–0.95). Importantly, no fracture risk reduction was noted in SRs/MAs exclusively evaluating community-dwelling individuals or in those on vitamin D alone compared with placebo/control. The authors concluded individual participant data metaanalyses of patients on Ca/D with sufficient follow-up periods, and subgroup analyses, would unravel determinants for a beneficial response to supplementation.

There is evidence for an effect of vitamin D supplementation for the primary prevention of minimal trauma fractures, including hip fractures, in postmenopausal women and older men, but only when combined

with calcium supplements. The effect size for primary fracture prevention is likely to be larger for those with a higher background fracture risk, including those who have the lowest serum levels of 25(OH)D (<25 nmol/L) and in institutionalized patients. In women and men aged >50 years, the combination of vitamin D with calcium, but not vitamin D alone, has modest effects in preventing any nonvertebral and hip fractures ranging from 5% for any fractures in the Cochrane review [109] to 30% for hip fractures in the National Osteoporosis Foundation metaanalysis [124]. The daily dose of vitamin D should be at least 800 IU (20 µg). High single annual or monthly doses of vitamin D may increase falls and, possibly, fractures in older men and women and are, therefore, not recommended.

## 9. Safety

### 9.1 Vitamin D

Vitamin D alone is safe at daily doses of 2000 IU per day and is likely to be safe up to 4000 IU per day. However, the recent studies [116,117] showing an increased risk for falls following an annual dose of 500,000 IU, a monthly dose of either 60,000 IU or 24,000 IU vitamin D<sub>3</sub> when combined with 300 µg calcidiol (25(OH)D), means the safety of high-dose vitamin D supplementation warrants further study (see before).

### 9.2 Calcium and vitamin D

The safety of the combination of calcium and vitamin D has not been comprehensively assessed; however,

concern has recently been raised regarding the safety of calcium supplements. One RCT ( $n = 1471$ ) [128] and one metaanalysis using either individual patient or trial data [129] have reported on cardiovascular (CV) adverse events associated with calcium supplements compared with placebo or calcium and vitamin D in elderly, postmenopausal women. In the trial, there was no significant difference between groups in the risk of any CV event (angina, chest pain, myocardial infarction [MI], or sudden death), risk of stroke, or risk of sudden death. The risk of MI was not significant between groups for a number of validated events (RR, 1.49; 95% CI, 0.86–2.57). For the primary endpoint (risk of MI, stroke, or sudden death), there was no significant difference in the number of validated events (RR, 1.21; 0.84–1.74); however, the rate ratio showed a significant increase associated with calcium (RR, 1.43; 1.01–2.04;  $P = .043$ ).

In the metaanalysis of individual patient data, the risk of MI was increased (HR, 1.31; 95% CI, 1.02–1.67;  $P = .035$ ) [129]. The metaanalysis of trial level data showed similar results, with an increased incidence of MI in those allocated to calcium (RR, 1.27; 1.01–1.59;  $P = .038$ ) [128]. However, it should be noted that all trials were designed to assess the effect of calcium on BMD and the power to detect a clinical effect for CV outcome measures is not reported. In addition, it remains unclear whether the addition of vitamin D might attenuate the proposed adverse CV effects of calcium supplements. Calcium supplement use has also been associated with an increased risk of incident coronary artery calcification (RR, 1.20; 95% CI, 1.7–1.39); however, in the same study, high total calcium intakes (diet and supplements) were associated with a decreased risk of incident atherosclerosis [130].

### 9.2.1 Secondary fracture prevention with vitamin D or calcium and vitamin D

Either vitamin D alone or the combination of calcium and vitamin D is ineffective in reducing fractures in patients who have already had a minimal trauma fracture. A large study of 5292 women and men (15%) aged  $>70$  years with prevalent minimal trauma fractures examined secondary fracture prevention using 800 IU cholecalciferol (vitamin D<sub>3</sub>) per day versus 1000 mg calcium per day, or the combination of calcium and vitamin D<sub>3</sub>, or placebo over 2–5.2 years [131]. Thirteen percent of participants had a new minimal trauma fracture, 183 (26%) of which were hip fracture. The incidence of new minimal trauma fractures did not differ significantly between participants allocated calcium and those who were not (HR, 0.94; 95% CI, 0.81–1.09); between participants allocated vitamin D<sub>3</sub> and those who were not (1.02; 0.88–1.19); or between those allocated combination treatment and those assigned placebo (HR for interaction term, 1.01;

0.75–1.36). The groups did not differ in the incidence of all-new fractures, fractures confirmed by radiography, hip fractures, death, number of falls, or quality of life. This trial was notable for low adherence (54.5%) with tablets at 2 years and the ability of patients to start other antiosteoporotic therapy during the study. Compliance with tablets containing calcium was also significantly lower (difference: 9.4%; 6.6–12.2), partly because of gastrointestinal symptoms.

In a primary care, nurse-led study of 3314 women aged  $\geq 70$  years with one or more risk factors for hip fracture, including a previous fracture, daily oral supplementation with 1000 mg calcium and 800 IU cholecalciferol was given for 2 years in an open randomized trial [132]. Adherence with therapy at 2 years was low (55%). After a median follow-up of 25 months (range 18–42 months), clinical fracture rates were lower than expected in both groups but did not significantly differ for all clinical fractures (HR, 1.01; 95% CI, 0.71–1.43). The odds ratio for hip fracture was 0.75 (0.31–1.78). The odds of a woman having a fall at 6 and 12 months also did not differ between groups.

## 9.3 Conclusion

Despite the limitation of poor adherence in both studies, there is no evidence that calcium or vitamin D, either alone or in combination, is effective in reducing fractures in older women and men with preexisting minimal trauma fractures. In these individuals, antiosteoporosis drugs should be used instead. Interestingly, in women treated with commonly used antiresorptive drugs, treatment responses are improved in those with optimal serum 25(OH)D levels. In an Italian study, 1515 women with postmenopausal osteoporosis treated with antiresorptive drugs (alendronate, risedronate, raloxifene) for 13.1 months with an adherence rate  $>75\%$  were classified as vitamin D deficient ( $<20$  ng/mL or 50 nmol/L) ( $n = 453$ ) or replete [133]. Vitamin D-deficient or Vitamin D-replete subjects differed significantly in annualized spine and hip BMD changes adjusted for confounding factors. One hundred and fifty-one patients suffered from a new incident clinical fracture. The adjusted odds ratio for incident fractures in vitamin D-deficient compared with vitamin D-replete women was 1.77 (1.20–2.59;  $P = 0.004$ ).

Thus, a target serum level  $\geq 20$  ng/mL or 50 nmol/L should be aimed for in women and men on antiresorptive drugs to optimize skeletal responses. Most patients will require 800–2000 IU cholecalciferol per day to achieve these levels [134]. In addition, such levels will minimize the risk of hypocalcemia, particularly following parenteral antiresorptive therapy [135,136], and may reduce the severity of the acute-phase reaction

commonly seen after the first intravenous infusion of zoledronic acid [137].

## 10. Effects of active vitamin D analogs on fractures

There is no evidence that related vitamin D compounds (analogs) have advantages in terms of effectiveness or reduced incidence of adverse effects compared with vitamin D. Four small trials of alfacalcidol, of which three were in Japan by the same author in patients with neurological diseases [138–141], suggest that alfacalcidol was effective in reducing the incidence of hip fractures in older people with and without preexisting osteoporotic fractures (4 trials, 371 participants, RR, 0.18; 95% CI, 0.05–0.67). Positive results from these small studies need to be confirmed by other investigators in larger studies. Other small studies that examined effects on fractures at other skeletal sites, which compared alfacalcidol with calcium (with or without vitamin D), or alfacalcidol and calcium with calcium, were inconclusive [142].

Two trials compared calcitriol with calcium [143,144]. Overall, there was no statistically significant effect on the incidence of nonvertebral fractures (2 trials,  $n = 663$  participants; RR, 1.19; 95% CI, 0.09–15.77) or vertebral deformities (2 trials,  $n = 556$  participants; RR, 1.69; 95% CI, 0.25–11.28). In Tilyard et al. [144], the duration of treatment was critical. At the end of 1 year, no effect could be shown. Fewer vertebral deformities occurred in the calcitriol group during the second year (RR, 0.47; 95% CI, 0.26–0.87), and during the third year (RR, 0.28; 95% CI, 0.15–0.52). Thus, the effect of calcitriol in fracture prevention is unclear, with the best evidence for effectiveness coming from the trial where vertebral deformities were significantly reduced only in the second and third years. However, the use of calcitriol was associated with a statistically significant increase in the risk of hypercalcemia, so it is not recommended as a first-line drug to treat osteoporosis.

### 10.1 The anabolic vitamin D analogs, 2MD

Most antiosteoporosis drugs, including active vitamin D analogs, act by inhibiting bone resorption. 2MD (2-methylene-19-nor-(20S)-1 $\alpha$ ,25-dihydroxyvitamin D<sub>3</sub>) is a novel vitamin D analog that is a potent bone formation stimulating drug in vitro and also in vivo in an ovariectomized rat model [145]. However, in a randomized, double-blind, placebo-controlled study of osteopenic women, although daily oral treatment with 2MD caused a marked increase in markers of bone formation, it did not significantly increase BMD [146]. In this study, 2MD

also caused a marked increase in bone resorption, so the predominant effect of 2MD was to stimulate bone remodeling. This critical difference between the preclinical and clinical studies could reflect underlying differences in bone metabolism, including continuing skeletal modeling in the rat.

### 10.2 The vitamin D analogs, eldecalcitol

Eldecalcitol is an analog of 1,25(OH)<sub>2</sub>D<sub>3</sub> that in a double-blind, placebo-controlled trial with vitamin D supplementation in patients with osteoporosis increased lumbar spine BMD over 12 months in a dose-dependent manner. There was also a lower incidence of hypercalcemia in the 0.75  $\mu$ g/day group than in the highest dose group (1  $\mu$ g/day) [147]. In a 3-year double-blind, active comparator superiority trial, 1054 patients with osteoporosis were randomized to receive daily oral 0.75  $\mu$ g eldecalcitol or 1.0  $\mu$ g alfacalcidol to prevent fractures due to osteoporosis. The primary endpoint was reduction in vertebral fractures. After 3 years of treatment, the risk of vertebral fractures was 26% lower with eldecalcitol (absolute risk reduction (ARR) = 4.1%). Eldecalcitol also reduced bone remodeling rate and increased BMD more than alfacalcidol. The secondary endpoint of a reduced incidence of nonvertebral fractures was achieved predominantly due to a reduction in fractures of the distal radius by 71% compared with alfacalcidol (ARR 2.5%). However, increases in serum and urinary calcium were higher in the eldecalcitol group [148] and occurred in 21.0% and 25.6% of participants, respectively.

## 11. Large randomized controlled trials of vitamin D supplementation

At least seven large ( $n \geq 1000$ ) RCTs of vitamin D supplementation with a variety of nonskeletal primary outcomes have recently been performed or are ongoing. None target population groups likely to have low vitamin D levels and have recruited low numbers of participants with baseline 25(OH)D levels <25 nmol/L, in whom vitamin D is likely to be most effective [149] (Table 70.1). In addition, some studies are using doses equivalent to 60,000 IU vitamin D<sub>3</sub> per month, so it will be important to also examine safety outcomes carefully, including falls.

The D-Health Trial is an Australia randomized placebo-controlled trial, with planned intervention for 5 years and a further 5 years of follow-up through linkage with health and death registers. Two thousand one hundred and thirty-five participants aged 65–84 years are being treated with monthly oral doses of 60,000 IU

**TABLE 70.1** Proportions of participants below serum 25(OH)D concentrations associated with vitamin D insufficiency and deficiency at baseline in recent large studies.

Study	Baseline serum 25(OH)D	Serum 25(OH)D <25 nmol/L	Serum 25(OH)D <50 nmol/L
	Mean (SD)	N (%)	N (%)
ViDA	63 (24)	161 (3%)	1,534 (30%)
VITAL	77 (25)	621 (2.4%) <sup>a</sup>	3,337 (12.9%) <sup>a</sup>
D-health	80 (25)	298 (1.4%) <sup>a</sup>	2,558 (12%) <sup>a</sup>

<sup>a</sup>Measured in a subset or calculated.

of cholecalciferol or placebo. The primary outcome is all-cause mortality. Secondary outcomes are total cancer incidence and colorectal cancer incidence. Other outcomes include falls and fractures [150]. Vitamin D had no effect on falls (odds ratio [OR], 1.02; 95% CI, 0.95 to 1.10). There was, however, a significant interaction with body mass index (BMI) (P-interaction = 0.001), with vitamin D increasing falls risk among people with BMI <25 kg/m<sup>2</sup> (OR, 1.25; 95% CI, 1.09–1.43) [151].

## 12. Mendelian randomization studies

Mendelian randomization studies use genetic markers associated with variations in 25(OH)D identified by genome-wide association studies (GWAS). A limitation of randomized trials is that they typically investigate short-term to medium-term interventions in a risk factor. However, for most diseases, it is probable that the benefit of short-term interventions in a risk factor will be less substantial than lifelong changes, which will be identified in Mendelian randomization studies. The results from Mendelian randomization studies estimating dose–response relationships for vitamin D with coronary heart disease, stroke, and all-cause mortality confirm earlier cohort studies showing nonlinear associations with measured 25(OH)D [152]. A recent genome-wide association study identified 143 independent loci associated with serum 25(OH)D concentration, representing 10.5% of its variation [153]. As it is not practical or financially possible to conduct sufficiently large RCTs of vitamin D supplementation in vitamin D–deficient populations, Mendelian randomization studies are likely to provide the strongest evidence on vitamin D and disease, including fractures and BMD.

## 13. Conclusions and future directions

There is mixed evidence on the effectiveness of vitamin D supplementation for the prevention of bone loss and minimal trauma fractures in postmenopausal women and older men. There is likely to be a benefit on primary fracture prevention for those with the highest background fracture risk, including those patients who have inadequate serum levels of 25(OH)D and institutionalized patients, but only when combined with calcium supplements. There is little evidence that vitamin D alone can prevent fractures, and no evidence that the combination of calcium and vitamin D, or either alone, can prevent fractures in patients with preexisting minimal trauma fractures. Recent large trials of vitamin D supplementation with multiple health outcomes, including fractures, contained only small proportions of participants with vitamin D deficiency or insufficiency. Because trials in large populations with vitamin D deficiency are not feasible because of ethical issues and expense, consideration should be given to pooling individual patient data from these studies to examine the effects of vitamin D supplementation on fractures in those with vitamin D deficiency.

The mechanisms occurring in muscle and bone, whereby a high single dose of vitamin D may result in the unexpected finding of falls and fractures, respectively, need to be determined. In addition, the role of recently identified genetic variants in explaining the high variability of clinical responses of serum 25(OH)D concentrations to either UVB exposure or to vitamin D supplementation needs to be elucidated using Mendelian randomization studies. Other less common genetic variants that may also affect serum 25(OH)D levels need to be identified to determine individualized doses of vitamin D supplements to attain optimal target levels of serum 25(OH)D. Finally, the links between the vitamin D and sex steroid axes in regulating age-related bone loss in both sexes need to be elucidated.

## 14. Summary points

- Vitamin D is a threshold nutrient, with a threshold in vitamin D status below which disease risk increases and vitamin D supplementation is beneficial.
- Recent RCTs have shown vitamin D supplementation alone increases BMD in individuals with baseline serum 25(OH)D concentrations <30 nmol/L.
- There is also likely to be a benefit on primary fracture prevention for those with the highest background fracture risk, including those patients who are

vitamin D deficient and institutionalized patients, but only when combined with calcium.

- Daily or monthly doses of vitamin D alone do not prevent fractures in community-dwelling, vitamin D-replete older adults, nor can the combination of calcium and vitamin D, or either alone, prevent fractures in patients with preexisting minimal trauma fractures.
- Mendelian randomization studies create new opportunities to examine the effects of vitamin D on bone health.

# Adult vitamin D deficiency—fracture and fall prevention: findings from randomized controlled trials

Bess Dawson-Hughes<sup>1</sup> and Heike A. Bischoff-Ferrari<sup>2</sup>

<sup>1</sup>Bone Metabolism Laboratory, Jean Mayer USDA Human Nutrition Research Centre on Aging, Boston, MA, United States <sup>2</sup>Department of Geriatrics and Aging Research, University Hospital Zurich and City Hospital Zurich, University Hospital Zurich, Zurich, Switzerland

## OBJECTIVES

- Characterize the population of older adults that may benefit from supplemental vitamin D.
- Summarize recent evidence that vitamin D affects fall risk.
- Define the pattern of the association of circulating 25-hydroxyvitamin D (25(OH)D) levels with fall risk and estimate the 25(OH)D levels associated with minimal risk of falling.
- Summarize current evidence linking vitamin D supplementation with fracture risk in older adults and identify the dose of supplemental vitamin D that is most likely to lower fracture risk.
- Consider the potential complementary role of combined vitamin D and calcium supplementation in reducing fracture risk.

## 1. Introduction

Falls have many causes and many consequences. Leading causes, in descending order of importance, include muscle weakness, history of falls, gait deficit, balance deficit, use of assistive device, visual defect, arthritis, impaired activity of daily living, depression, cognitive

impairment, and age >80 years [1]. With aging, fall rates increase by 10% per decade (on an absolute scale) and one in three community-dwelling people over age 65 and one in two over age 80 fall each year [2]. The consequences of falls in older adults are serious. One in five falls require medical intervention, and serious injuries occur with 10%–15% of falls; for instance, 5% of falls result in a fracture and 1%–2% in a hip fracture. Moreover, over 90% of fractures occur as a result of a fall. It is well known that falls may lead to psychological trauma often described as fear of falling [3]. After their first fall, about 30% of persons develop fear of falling that results in self-restriction of activities and decreased quality of life [4]. A mitigating effect of vitamin D on fall risk was initially suspected because of the established link between severe vitamin D deficiency and proximal muscle weakness and because of evidence that vitamin D replacement improves balance. The specific role that vitamin D plays in muscle strength and balance, and athletic performance will be addressed in Chapters 29 and 38 respectively, whereas this chapter will focus on falls.

Incident fractures have enormous health and economic consequences. Fractures are estimated to increase from 2.05 to >3 million between 2005 and 2025 in US adults aged 50 years and older, with associated costs in the first year after the fracture of between \$16.9 and \$25.3 billion [5]. The older adult population is expanding, and the cost of healthcare in the United States, currently at 1.5 trillion dollars per year, is rising at an

alarming rate. In this chapter, we will review the evidence, derived largely from randomized, controlled clinical trials, linking vitamin D supplementation with risk of fracture, considering the roles of dose, dose frequency, initial and achieved 25(OH)D levels, and the presence or absence of concurrent calcium supplementation. Compatible with the Institute of Medicine (now the National Academy of Medicine) definitions [6], vitamin D insufficiency is defined by a 25(OH)D level in the range of 20–50 nmol/L (8–20 ng/mL); levels below this range are considered deficient and those above it sufficient.

## 2. Vitamin D and falls

Much of the early evidence related to whether supplemental vitamin D affects fall risk was synthesized in a 2009 metaanalysis of randomized, double-blind, placebo-controlled vitamin D intervention trials [7,8]. This metaanalysis included eight trials in 2426 individuals in whom high quality falls data were acquired prospectively, and mean age of participants was  $\geq 65$  years [9–16]. Baseline 25(OH)D levels in these trials were in the range of 25–60 nmol/L with the exception of one trial in which it was 76 nmol/L. In the eight trials, there was a significant 27% reduction in odds of falling with vitamin D treatment overall [odds ratio 0.73 (95% CI, 0.62–0.87)], a 34% reduction among trials testing doses in the range of 700–1000 IU per day [0.66 (0.53–0.82)], and no significant reduction in trials testing lower doses ranging from 200 through 600 IU per day [1.14 (0.69–1.87)] [8]. This analysis suggests that in vitamin D–insufficient older adults, supplementation with 700–1000 IU per day will lower risk of falling, whereas lower doses are ineffective.

In 2015, after the publication of this metaanalysis, two falls trials were published. A 2-year trial testing 800 IU per day of vitamin D<sub>3</sub> versus placebo found no significant benefit from supplementation in 409 community-dwelling Finnish women, aged 70–80 years [17]. The mean serum 25(OH)D level at baseline in this trial was 67.5 nmol/L, indicating that most of the women were vitamin D replete at entry into the trial. In contrast, a trial in Brazilian women with a low initial mean 25(OH)D level of 38 nmol/L found that treatment with 1000 IU per day of vitamin D<sub>3</sub> increased the serum 25(OH)D level to 69 nmol/L and significantly reduced fall risk [odds for falling in the placebo group compared with the treated group was 1.95 (95% confidence interval 1.23–3.08)] [18].

Between 2017 and 2021, the effect of oral vitamin D<sub>3</sub> on fall risk was reported in three large clinical trials (megatrials) testing doses of vitamin D > 1000 IU per day (two of the three used bolus dosing) [19–21] and in a fourth large trial testing 1000 IU per day [22]. In

the first, the vitamin D assessment (ViDA) study in New Zealand, 5110 adults aged 50–84 years were treated with an initial oral dose of 200,000 IU of vitamin D<sub>3</sub> followed by 100,000 IU per month (equivalent to 3333 IU per day) or placebo for 3.4 years. The mean serum 25(OH)D level was 63 nmol/L at baseline, and it increased to 135 nmol/L in the supplemented group. The supplementation did not alter the risk of first fall (HR 0.99 [95% CI, 0.92–1.05]). In the second megatrial, the VITAL study, treatment with 2000 IU of vitamin D<sub>3</sub> per day versus placebo for 5.3 years had no significant effect on risk of falling in 25,871 adults mean age 67.1 years [20]. In participants in the vitamin D group who had paired 25(OH)D measurements at baseline and 1 year, the serum 25(OH)D level started at 74 nmol/L and increased to 104 nmol/L. In the third megatrial, fall risk was also assessed in a survey of 16,000 randomly selected participants in the Australian D-Health Trial [21]. In this trial, men and women aged 60–84 years were randomized to treatment with 60,000 IU of vitamin D<sub>3</sub> per month or an inactive placebo. In the subset measured, intra-trial 25(OH)D levels were 77.5 in the placebo group and 114.8 nmol/L in the supplemented group. After 4.3 years of the intervention, the odds ratio for fall risk reduction was not significant (1.02 [0.95–1.10]). Falls were assessed by self-report.

The fourth megatrial, the STURDY study, was the only recent megatrial in which fall prevention was the primary endpoint [22]. This study had two phases, a 2-year dose finding phase followed by a 2-year confirmatory phase. In the dose-finding phase, participants at high risk for falling were randomly assigned to treatment with 1,000, 2,000, or 4000 IU of D<sub>3</sub> per day or 200 IU per day (control). Over 2 years of treatment, the most promising dose for fall prevention appeared to be the 1000 IU per day dose. This dose and the control dose were carried forward in the 2-year confirmatory phase in 674 adults aged 70 years and older [22]. The participants had an initial mean 25(OH)D level of 55 nmol/L that increased to 80 nmol/L in the 1000 IU arm. The confirmatory phase of this trial was null, with a hazard ratio for first fall of 0.94 [0.76–1.15].

How can we reconcile the large and inconsistent body of randomized, controlled trial evidence indicating that supplemental vitamin D does and does not reduce fall risk? This question can be considered in the context of several design features of these studies.

### 2.1 Study population 25(OH)D levels

As pointed out by Morris et al. [23], a basic principle of nutrition is that most nutrients have a nonlinear association with optimal physiological function. Low nutrient levels result in poor function; there are a fairly

broad range of levels that result in optimal functioning, and high levels result in suboptimal function [23]. This pattern was in fact observed in relation to fall risk in a recent secondary analysis of the STOP/IT trial in community-dwelling men and women aged 65 years and older [24]. Participants were treated with either 700 IU of vitamin D<sub>3</sub> plus 500 mg of calcium or double placebo daily for 3 years. In an analysis of all participants combined ( $n = 410$ ), we examined the association of the cumulative mean intra-trial 25(OH)D (defined as the mean of biannual plasma 25(OH)D measurements up to and including the time of the first fall) with risk of falling. There was a statistically significant nonlinear U-shaped pattern in the association of cumulative mean 25(OH)D levels with risk of first fall (Fig. 71.1) [24]. Falls were greater in participants with intra-trial 25(OH)D levels below 50 nmol/L, were at their nadir at 25(OH)D levels in the range of 50–100 nmol/L, and were more frequent at 25(OH)D levels  $\geq 100$  nmol/L. A limitation of the analysis is that only 24 participants had intra-trial mean 25(OH)D levels  $>100$  nmol/L.

Although none of the trials published to date limited enrollment to deficient and insufficient populations, participants enrolled in the earlier trials frequently had insufficient and deficient 25(OH)D levels. In contrast, participants enrolled in the more recent trials were generally replete in vitamin D because the trials were conducted in locations in which vitamin D supplementation and food fortification had become commonplace. As a consequence, mean 25(OH)D levels at entry, ranging from 63 to 77 nmol/L in the megatrials, were consistently in the nadir region of the fall risk curve (Fig. 71.1). Thus, recent megatrials do not address the question of whether vitamin D supplementation affects fall risk in insufficient or deficient adults.

**FIGURE 71.1** Intra-trial mean plasma 25(OH)D and risk of falling from Dawson-Hughes et al. [24], with permission. Analyses, adjusted for age (half decades), sex, and calcium intake, are estimated from quadratic (dashed line) and three-piecewise logistic regression (solid line).

## 2.2 Dose size

Another feature of recent megatrials [19–21] is that they tested doses that were higher than the amounts of 700–1000 IU per day, shown earlier to reduce risk of falling in vitamin D–insufficient older adults [25]. These studies confirm that higher doses do not add value in replete individuals.

## 2.3 Safety signals

The recent megatrials, with their replete starting 25(OH)D levels and high dosing, may have placed some participants in the portion of the curve in which an adverse effect on falls is expected (Fig. 71.1). While the D-Health study overall was null for fall prevention, in the subset of 4681 participants with BMI levels  $<25$  kg/m<sup>2</sup>, supplementation with 60,000 IU of D<sub>3</sub> per month significantly *increased* risk of falling (HR 1.25 [1.09–1.43]) [21]. The achieved 25(OH)D level in this subset was not reported, but it is plausible that it was higher than the mean level achieved by participants with BMI  $\geq 25$  kg/m, because hepatic 25-hydroxylase (CYP2R1) activity is reduced in obesity [26]. Evidence that high-dose vitamin D increases fall risk has been documented in several earlier studies. Bischoff-Ferrari treated older adults at high risk for falling with 60,000 versus the standard dose of 24,000 IU of D<sub>3</sub> per month (equivalent to 2000 vs. 800 IU per day) and found significantly more falls in the higher dose group [27]. Additionally, Smith et al. tested multiple oral doses of vitamin D<sub>3</sub> ranging from 400 to 4800 IU per day and found that there were more falls in the dose groups that achieved mean 25(OH)D levels  $>103$  nmol/L [28]. In contrast, the lowest rate of falls was seen at the doses resulting in achieved 25(OH)D levels in the range of 88–103 nmol/L [28].

## 2.4 Dose frequency

Another consideration is whether “bolus” dosing has the same physiologic effect as an equivalent dose given daily. This issue came into focus with the publication by Sanders et al. who administered a single oral dose of 500,000 IU of vitamin D<sub>3</sub> or placebo annually for 4 years to 2256 women aged 70 years and older [29]. To the dismay of many, there were significantly more falls (and fractures) in the vitamin D group than in the placebo group (HR 1.16, 95% CI, 1.06–1.28). It is difficult to determine whether this untoward outcome resulted from the infrequent dosing, the magnitude of the infrequent dose administered, or both.

## 2.5 Potential physiologic basis for adverse effect of bolus doses and high daily doses of vitamin D

There is a physiologic basis for suspecting that bolus dosing and high daily dosing are counterproductive. Like modest daily dosing, bolus dosing and high daily dosing of vitamin D<sub>3</sub> effectively raise the circulating 25(OH)D concentration, but bolus dosing and high daily dosing have other effects on vitamin D metabolism. As reviewed recently by Mazess [30], bolus doses activate 24-hydroxylase (CYP24A1), which promotes conversion of 25(OH)D to the inactive metabolite, 24,25(OH)<sub>2</sub>D, thus reducing the substrate for the generation of the active metabolite, 1,25(OH)<sub>2</sub>D. It appears that both intermittent high dosing *and* high daily dosing of vitamin D (specifically 2000 to 3000 IU per day producing 25(OH)D levels  $\geq 100$  nmol/L) stimulate the production of fibroblast growth factor 23 (FGF23) [31,32], a compound that activates 24-hydroxylation (CYP24A1), which increases the catabolism of 1,25(OH)<sub>2</sub>D (and also reduces its production) [33]. The expected net effect of bolus dosing and of high daily dosing is higher circulating levels of 25(OH)D but lower levels of the active metabolite, 1,25(OH)<sub>2</sub>D. It is plausible that bolus dosing and high daily dosing with vitamin D activate a counter-regulatory endocrine response to prevent vitamin D toxicity and in so doing, lower circulating 1,25(OH)<sub>2</sub>D levels. The resulting lower 1,25(OH)<sub>2</sub>D levels may contribute to the observed increased risk of falling. Additional evidence is needed to support the clinical relevance of these proposed alterations in vitamin D metabolism.

## 3. Vitamin D and fracture risk

### 3.1 Bone mineral density

Low bone mineral density (BMD) is an established risk factor for fracture, and vitamin D supplementation has been shown in several studies to affect BMD in insufficient and deficient older adults. Ooms et al. treated 348 women aged 70 years and older with 400 IU of vitamin D<sub>3</sub> or placebo for 2 years [34]. In the vitamin D group, the mean serum 25(OH)D level was 27 nmol/L at baseline and 62 nmol/L on treatment. They found that supplementation significantly reduced bone loss at the femoral neck. Similarly, in the STOP IT trial, treatment with 700 IU of vitamin D<sub>3</sub> plus 500 mg of calcium daily for 3 years reduced bone loss from the spine and hip in 381 men and women aged 65 years and older [35]. Macdonald et al. examined the effects of 400 IU and 1000 IU per day of vitamin D<sub>3</sub> versus placebo on 1-year change in BMD in 265 older men and women and found that the higher dose modestly

decreased bone loss from the hip, whereas the 400 IU dose had no effect on hip BMD, when compared with placebo [36]. The study population was largely insufficient, with a mean baseline 25(OH)D level of 34 nmol/L. Two more recent trials have demonstrated that supplemental vitamin D in doses of 800 IU per day and 50,000 IU twice monthly for 1 year [37] and in a dose of 100,000 IU per month for 2 years [38] had no significant effect on BMD in vitamin D sufficient older adults with starting 25(OH)D levels of 52.5 nmol/L and 55 nmol/L, respectively. Collectively, these studies indicate that vitamin D supplementation modestly reduces bone loss in insufficient older populations, but not in those with adequate 25(OH)D levels.

### 3.2 Fractures

Vitamin D repletion is expected to be effective in lowering fracture risk in vitamin D—insufficient and vitamin D—deficient adults because it lowers risk of falling and improves BMD, but despite this, the evidence linking supplemental vitamin D to fracture risk reduction is inconsistent. Many randomized controlled trials have been performed to determine the effect of vitamin D on fracture risk. They have tested different doses, different dose frequencies, and interventions that involved vitamin D alone and vitamin D in combination with calcium supplementation. The earlier trials were conducted before the era of widespread vitamin D supplementation when substantial proportions of the general older population were insufficient. These earlier trials generally tested modest daily doses of vitamin D (up to 1000 IU per day) versus placebo on incident fracture, and they often included a calcium supplement along with the vitamin D. In contrast, recent vitamin D intervention trials have tended to test higher doses of vitamin D that were given daily or at less frequent intervals and have not included supplemental calcium. There have been as many metaanalyses as there are trials; we will examine in some detail the findings of two of these metaanalyses, an early individual participant-level metaanalysis of trials published between 1992 and 2010 [39] and a recent metaanalysis that includes trials published through 2018 [40].

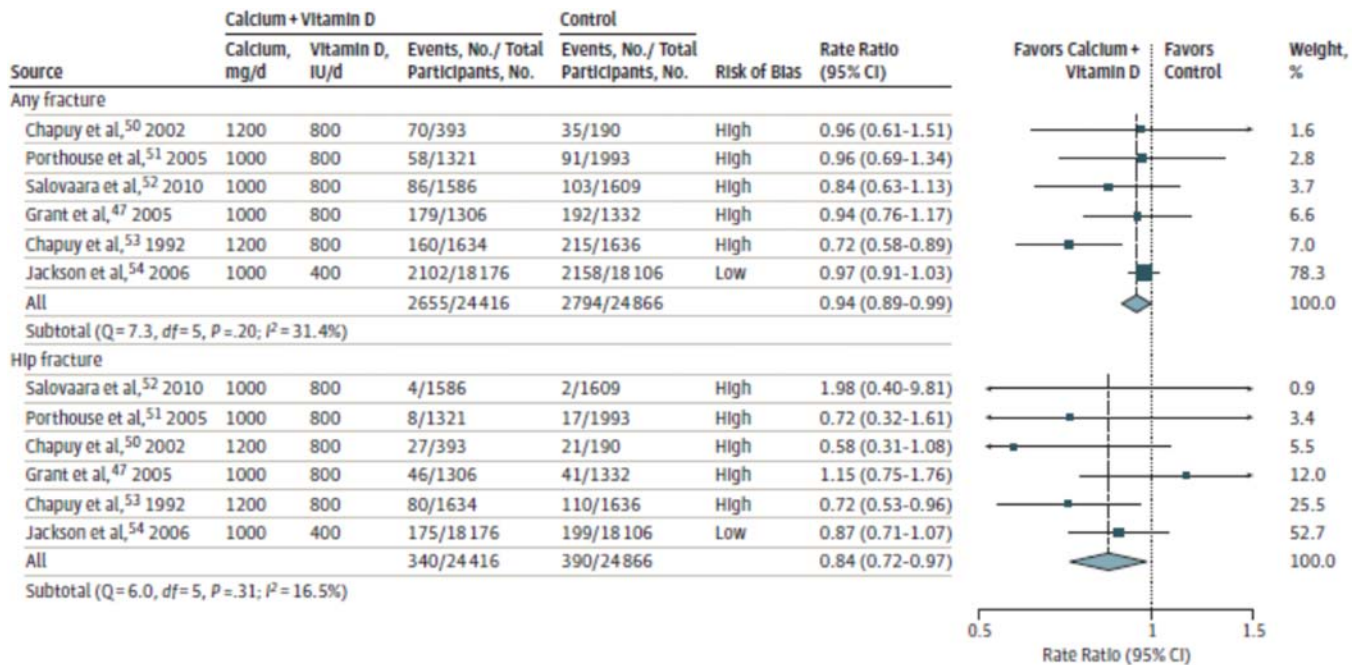

The earlier pooled analysis focused on the role of the dose administered and the actual intake of vitamin D (the product of administered dose and proportion taken) during the trial [39]. This detailed analysis was possible because individual participant-level data from the 11 included clinical trials were pooled. This analysis involved 31,022 persons, mean age 76 years, 91% of whom were women. Vitamin D supplements were given in varying amounts and at different intervals (daily, weekly, every few months). There were 1111 incident

hip fractures and 3770 non-vertebral fractures during these trials. The mean baseline 25(OH)D level was approximately 47 nmol/L, indicating that over one half of the study population was insufficient at entry into the trials. Overall, supplementation resulted in a non-significant risk reductions of 7% in non-vertebral fractures (0.93 [0.87 to 0.99]), 10% in hip fracture (hazard ratio [HR] 0.90; 95% CI, 0.80–1.01). When examined by quartiles of actual vitamin D intake during the trial (calculated as the product of dose administered X proportion consumed), there was a significant reduction in fracture risk only in the highest intake quartile. The median vitamin D intake in this quartile was 800 IU per day (range 792–2000 IU per day) [39]. The fracture risk hazard ratios in this quartile were 0.86 (95% CI, 0.76–0.96) for non-vertebral fracture and 0.70 (95% CI, 0.58–0.86) for hip fracture. This meta-analysis suggests that supplementation with 800 IU per day will lower non-vertebral fracture risk and hip fracture risk in older adults with a mean 25(OH)D level below 50 nmol/L. Notably, the majority of the included trials co-administered calcium with the vitamin D.

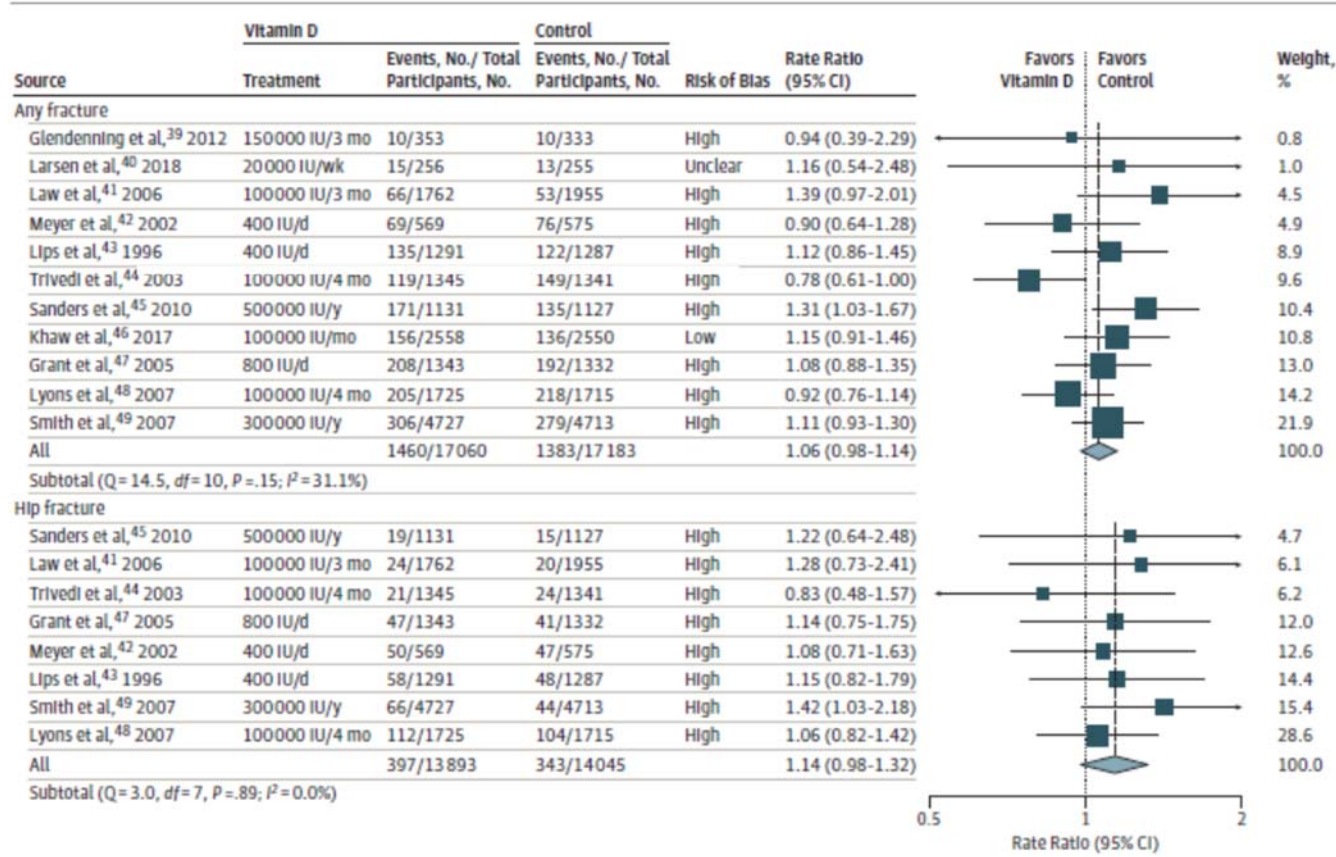

A more recent meta-analysis of randomized, placebo-controlled trials carried out by Yao et al. examined the impact of the combination of vitamin D plus calcium and vitamin D alone (vs. placebo) on fracture risk [40]. Only trials that enrolled 500 participants or more were included. Six vitamin D plus calcium trials were included in the analysis, and they involved 49,282 participants with a total of 5449 non-vertebral fractures

and 730 hip fractures. Five of the six trials tested the dose of 800 IU per day plus 1000–1200 mg per day of calcium, and the sixth trial, the Women's Health Initiative, tested 400 IU per day plus 1000 mg per day of calcium. Overall there was a 6% reduction in any non-vertebral fracture risk [0.94 (0.89–0.99)] (Fig. 71.2, upper panel) and a 16% risk reduction in hip fracture [RR 0.84 (95% CI, 0.72–0.97)] (Fig. 71.2, lower panel). Although 25(OH)D levels were not reported in the Yao metaanalysis, five of the six trials included in the vitamin D plus calcium metaanalysis reported baseline 25(OH)D levels, and they were in the range of 21–50 nmol/L [41–45].

The 11 trials in the vitamin D alone metaanalysis of Yao et al. included 34,243 participants. There were 2843 incident non-vertebral fractures and 740 hip fractures. Of these, all 11 reported non-vertebral fractures and 6 reported hip fractures. There was a lot of variation in the vitamin D doses tested and in the dose frequency. Two of the 11 trials tested a dose of 400 IU per day [46,47], and the others tested higher doses at varying intervals (one dosed weekly, one monthly, four either every 3 or 4 months, and two annually). Only one of these trials tested a dose of 800 IU per day in insufficient older adults (baseline 25(OH)D level 38 nmol/L), and it was null [43]. The overall impact of supplementation in these trials was null, with a relative risk (RR) for any fracture of 1.06 (0.98–1.14) (Fig. 71.3, upper panel). In the six trials that assessed the effect of vitamin D alone on hip fracture risk, the RR was 1.14 (0.98–1.32),

**FIGURE 71.2** Metaanalysis of randomized clinical trials of supplementation with vitamin D plus calcium or no treatment for prevention of any fracture (upper panel) or hip fracture (lower panel), from Yao et al. [40] with permission.

reflecting no benefit and possibly suggesting potential harm (Fig. 71.3, lower panel). The subsequently published DO-HEALTH trial was consistent in finding no effect of 2000 IU of vitamin D per day on non-vertebral fracture risk in vitamin D–sufficient older adults [48].

4. Conclusions

In older adults who are vitamin D insufficient and deficient (defined as having 25(OH)D levels <50 nmol/L), supplementation to achieve a 25(OH)D level in the range of 50–100 nmol/L is likely to lower risk of falling. This 25(OH)D range can be achieved in most individuals through supplementation with 800 IU of vitamin D<sub>3</sub> per day. Older adults with levels of 25(OH)D in the optimal range of 25(OH)D will not reduce fall risk with supplementation. Vitamin D supplementation that achieves 25(OH)D levels greater than approximately 100 nmol/L are associated with increased risk of falling and should therefore be avoided. Intermittent high doses of vitamin D have either no effect or a deleterious effect on falling.

The physiologic basis for an increased fall risk at higher vitamin D doses is not yet established, but it may involve a counter-regulatory endocrine response to high 25(OH)D levels. It is sobering to consider that the null falls megatrials, many of which used bolus dosing, may represent a spectrum of beneficial and harmful individual responses that, when combined, appear as null effects.

In vitamin D–insufficient older adults, vitamin D in a dose of 800 IU per day together with calcium modestly reduced risk of non-vertebral fractures and, importantly, substantially reduced risk of hip fractures. Only one trial tested the dose of 800 IU per day of vitamin D alone in insufficient adults, and it was null [43]. Thus, we cannot conclude that 800 IU of vitamin D alone is effective in preventing fractures in insufficient older adults. There is now ample evidence that higher doses of vitamin D and infrequent dosing of vitamin D are not effective in lowering fracture risk. Current evidence indicates that in older adults with vitamin D insufficiency, daily supplementation with 800 IU of vitamin and an adequate intake of calcium is a rational and effective approach to reducing risk of falls and fractures.

## 5. Summary points

- Older adults most likely to benefit from supplemental vitamin D are those with circulating 25(OH)D levels in the insufficient and deficient ranges (below 50 nmol/L).
- In vitamin D insufficient older adults, supplemental vitamin D in the dose range of 700–1000 IU per day lowers risk of falls; lower doses are ineffective, and higher doses (daily or intermittent) may increase risk of falling.
- There appears to be a U-shaped association of circulating 25(OH)D levels with risk of falling in older adults. Fall risk appears to be minimal at circulating 25(OH)D levels in the range of 50–100 nmol/L and to increase progressively as levels drop below and also potentially as they rise above this range.
- Many earlier clinical trials tested the dose of 800 IU per day of vitamin D together with 1000 to 1200 mg per day of calcium in vitamin D–insufficient older adults. A metaanalysis of these trials revealed significant fracture risk reduction in non-vertebral fractures and in hip fractures. Only one trial tested 800 IU of vitamin D alone, and this trial was null. We cannot therefore conclude that vitamin D alone will reduce fracture risk.
- In conclusion, while 700–1000 IU per day of vitamin D can be expected to reduce fall risk, only 800 IU of vitamin D together with calcium has been demonstrated to reduce fracture risk in insufficient older adults. It therefore seems prudent to recommend the combination of around 800 IU of vitamin D and supplemental calcium to minimize risk of both falls and fractures in vitamin D–insufficient older adults.

## OBJECTIVES

- Review the results of randomized clinical trials investigating the effects of supplemental vitamin D versus placebo on bone mineral density.
- Review the results of randomized clinical trials investigating the effects of supplemental vitamin D versus placebo on incident fracture risk.
- Present the results of randomized controlled trials of the effects of supplemental vitamin D versus placebo on bone health measures, according to baseline serum 25-hydroxyvitamin D levels.
- Discuss the clinical patient population that may have skeletal benefits from vitamin D and calcium supplementation.

calcium absorption, improving mineralization of bone, reducing secondary hyperparathyroidism, and modifying bone turnover. Furthermore, extrarenal activation of 25-hydroxyvitamin D [25(OH)D] to 1,25-dihydroxy vitamin D [1,25(OH)<sub>2</sub>D] in bone has been linked to generation of osteoblast precursors [4,5]

Use of vitamin D supplements in the United States has increased markedly over the past 20 years with 36.9% of US adults aged 60 and over taking vitamin D supplements [6–8]. Although vitamin D supplements are widely used in the general population to benefit bone health, findings from randomized controlled trials (RCTs) have been inconsistent, as summarized in Table 72.1 [9,10,12–16].

## 1. Introduction: clinical and public health importance

Osteoporosis and vitamin D deficiency have been considered major public health problems (see Chapters 62, 63, 70, and 71). An estimated 53.6 million Americans have osteoporosis and/or low bone mass, which are associated with increased risk of fractures [1]. In the United States (U.S.), one in two women and one in four men aged 50 years and older will suffer an osteoporotic fracture, leading to excess morbidity and premature mortality [2,3]. As the population ages, there is an exponential rise in osteoporotic fractures [3]. Vitamin D may promote bone health by increasing intestinal

## 2. Findings from systematic reviews and metaanalyses

### 2.1 Systematic reviews and metaanalyses of supplemental vitamin D on incident fractures

Systematic reviews and metaanalyses have shown varying results of effects of supplemental vitamin D on bone mineral density (BMD) and fractures [17–24]. The 2011 US Preventive Services Task Force (USPSTF) summary of five RCTs (n = 14,583) concluded that vitamin D supplementation versus placebo was not associated with reduction in fractures [17–23]. An analysis of seven RCTs, including 68,500 older adults, in the Vitamin D Individual Patient Analysis of Randomized Trials (DIPART), also found that bolus or daily supplemental vitamin D (400 and 800 IU/day) alone did not

**TABLE 72.1** Large randomized controlled trials of supplemental vitamin D on fractures: daily and bolus dosing.

	Study	Participants	Intervention	Duration	25(OH)D levels	Key findings
Daily dosing	Lips et al. [9]	Netherlands: women and men $\geq 70$ years old, mean $\pm$ SD age $80 \pm 6$ , from both independent and residential facilities (n = 2578)	Oral vitamin D <sub>3</sub> 400 IU/day or placebo	3.5 years (median)	Baseline: 27.0 nmol/L in vitamin D <sub>3</sub> group and 26.0 nmol/L in placebo group Follow-up (3 years): 60 nmol/L in vitamin D <sub>3</sub> group and 23 nmol/L in placebo group	No effect on hip or peripheral fractures
	Bischoff-Ferrari et al. [10] DO-HEALTH	Europe: women and men $\geq 70$ years old, mean $\pm$ SD age $74.9 \pm 4.4$ (n = 2157)	Oral vitamin D <sub>3</sub> 2000 IU/day, omega-3 fatty acids 1000 mg/day, and strength-training exercise program alone and in combinations or placebo	3.0 years (median)	Baseline: $55.9 \pm 21$ nmol/L Follow up (3 years): 93.8 nmol/L in the vitamin D <sub>3</sub> groups and 60.9 nmol/L in the nonvitamin D <sub>3</sub> groups	No effect on nonvertebral fractures
	LeBoff et al. [11], VITAL	United States: women aged $\geq 55$ and men aged $\geq 50$ years old, mean $\pm$ SD age $67.1 \pm 7.1$ (n = 25,871)	Oral vitamin D <sub>3</sub> 2000 IU/day or placebo	5.3 years (median)	Baseline: $76.6 \pm 25$ nmol/L (n = 16,757) Follow up (2 years): 102.8 nmol/L in the vitamin D <sub>3</sub> group and 73.4 nmol/L in the placebo group	No effect on total, non-vertebral, or hip fractures or falls.
Bolus monthly dosing	Trivedi et al. [12]	Great Britain: women and men aged 65–85 years, mean $\pm$ SD age $74.8 \pm 4.6$ (n = 2686)	Oral vitamin D <sub>3</sub> 100,000 IU every 4 months or placebo	5 years	Follow up (4 years): $74.3 \pm 20.7$ nmol/L in the vitamin D <sub>3</sub> group, $53.4 \pm 21.1$ nmol/L in the placebo group	Reduced rate of first fracture by 22%, first fracture of hip/wrist/vertebral by 33%.
	Law et al. [13]	Great Britain: women and men in residential accommodation, mean age 85 (n = 3717)	Oral vitamin D <sub>3</sub> 100,000 IU every 3 months versus control	10 months (median)	Baseline: 59 nmol/L Follow up (1 month): 99 nmol/L Follow up (3 months): 77 nmol/L	No effect on nonvertebral fractures or falls.
	Khaw et al. 2017, Vitamin D assessment study, ViDA Trial [14]	New Zealand: women and men aged 50–84 years old, mean $\pm$ SD age $65.9 \pm 8.3$ years (n = 5110)	Oral vitamin D <sub>3</sub> 100,000 IU/month with initial oral dose of 200,000 IU or placebo	3.3 years (median)	Baseline: $63 \pm 24$ nmol/L Follow-up (6 months): $129 \pm 42$ nmol/L in vitamin D <sub>3</sub> group and $75 \pm 31$ nmol/L in placebo group	No effect on nonvertebral fractures or falls.

Bolus annual dosing	Smith et al. [15]	England: women and men $\geq 75$ years old, median age of 79.1 (n = 9440)	Intramuscular vitamin D <sub>2</sub> 300,000 IU/year or placebo	3 years	Baseline (n = 43): 141.0 $\pm$ 59.2 nmol/L Follow-up (4 months): 21% increase in the vitamin D <sub>2</sub> group (P = .15)	No effect on nonvertebral or wrist fractures. Slight increase in hip or femur fractures. No effect on falls.
	Sanders et al. [16]	Australia: community-dwelling women $\geq 70$ years old, median (IQR) age 76.0 (73.1–80.2), at high risk of hip fracture (n = 2256)	Oral vitamin D <sub>3</sub> 500,000 IU/year or placebo	3–5 years	Baseline: 49 nmol/L (median) Follow-up: 120 nmol/L at 1 month, 90 nmol/L at 3 months in the vitamin D <sub>3</sub> group	Increased rate of fractures by 26% and falls by 15%.

prevent fractures [25]. Another pooled analysis of 11 RCTs of oral vitamin D supplementation, with or without calcium, as compared with placebo or calcium alone, including 31,022 adults  $\geq 65$  years (91% females), found that there was a small 7% reduction in nonvertebral fractures and no reduction in hip fracture in those assigned to supplemental vitamin D [26]. However, in participants who were in the highest quartile of vitamin D intake (median of 800 IU/day), there was a 30% reduction in hip fracture risk and 14% reduction in nonvertebral fracture risk [26]. Of note, 8 out of 11 of these studies included coadministration of calcium. More recent systematic reviews and metaanalyses have found no benefit for supplemental vitamin D on the primary prevention of fractures, even in community-dwelling adults with low 25(OH)D levels [17–24,27–32].

The extensive review by the Institute of Medicine (IOM) committee in 2011 emphasized the need for more research from large RCTs to “test the effects of vitamin D on skeletal and nonskeletal outcomes” and “possible adverse effects where present” [32]. Since that time, a number of RCTs have been performed. In this chapter, we will review findings from large RCTs investigating the effects of supplemental vitamin D versus placebo on bone density and architecture and incident fractures in community-dwelling adults from around the world.

## 2.2 Systematic reviews and metaanalyses of supplemental vitamin D and calcium on incident fractures

In 2013, the USPSTF recommended *against* the daily supplementation with  $\leq 400$  IU of vitamin D<sub>3</sub> and  $\leq 1000$  mg of calcium for the primary prevention of fractures in community-dwelling postmenopausal women and concluded that there was insufficient evidence relative to benefits and risks of daily supplementation with  $>400$  IU of vitamin D<sub>3</sub> and  $>1000$  mg of calcium [18]. This was based heavily on the results of the Women’s Health Initiative Trial (WHI), in which daily supplemental vitamin D<sub>3</sub> 400 IU and calcium 1000 mg did not reduce hip or total fracture risk compared with placebo [33,34]. It should be noted that in addition to the interventions, 55.8% participants in the WHI took their own personal calcium and/or vitamin D supplements, as was permitted in this trial [33,34]. This RCT will be further reviewed in the following.

Since 2013, results of several, but not all, metaanalyses suggest that the coadministration of calcium and vitamin D may reduce fracture risk [20,24,28,32]. Weaver et al. performed a metaanalysis of RCTs of vitamin D plus calcium supplementation on fracture incidence

and found a 15% risk reduction of total fractures and a 30% risk reduction of hip fractures [20]. A Cochrane review found similar results with a 14% reduction in nonvertebral fractures and 16% reduction in hip fractures [32]. Finally, a 2019 metaanalysis of RCTs of combined supplementation with vitamin D and calcium found a 6% reduction in any fracture and 16% reduction in hip fractures [31]. A systematic umbrella review of metaanalyses of controlled trials found that the reduction of hip and any fracture risk with calcium and vitamin D cosupplementation is likely driven by findings in institutionalized individuals [24]. As the primary role of vitamin D is to increase absorption of calcium, adequate intakes of both vitamin D and calcium are necessary for bone health.

## 3. Current recommended intakes based on bone health goals

In 2011, after a comprehensive review, the IOM committee updated the recommended dietary allowance (RDA) of vitamin D and calcium for adult men and women with a goal of supporting bone health by optimizing calcium absorption [35]. Based on studies that found that maximal calcium absorption occurs at a serum 25(OH)D level between 30 and 50 nmol/L, the RDA for vitamin D was set at 600 IU/day for adults  $\leq 70$  years old. Using data from the winter season at high latitudes to minimize contributions from sunlight, a dose of 400 IU was predicted to result in a mean circulating 25(OH)D level of 60 nmol/L, with a lower confidence interval of 52.5 nmol/L. An RDA of 600 IU/day was selected to ensure that a level of 40–50 nmol/L is achieved in 97.5% of the population, given large interstudy variance, differences in 25(OH)D assays, and uncertainty of regression analyses.

The RDA for adults over 70 years old was set at 800 IU/day of vitamin D with a goal of reducing fracture risk [35]. At the time, and to some extent today, there was a lack of dose–response data and findings on effects of vitamin D supplementation without concurrent calcium versus placebo on fracture outcomes. Since aging is associated with decreases in intestinal calcium absorption, renal production of 1,25(OH)<sub>2</sub>D, and activation of vitamin D in skin, the IOM committee concluded a higher RDA of 800 IU/day was pertinent for this high fracture risk population, without increasing risk of adverse events.

In previous years, a number of specialty professional organizations, including the Endocrine Society, American Association of Clinical Endocrinologists, and Bone Health and Osteoporosis Foundation, have recommended a 25(OH)D level of  $\geq 75$  nmol/L for patients with osteoporosis [3,36,37]. This threshold was based

predominantly on physiological and observational studies, rather than on data from RCTs. In a small physiology study, Heaney and colleagues showed that administration of vitamin D, raising 25(OH)D levels from 50 to 87.5 nmol/L, resulted in a 65% greater gut absorption of calcium, compared with no supplemental vitamin D [38,39]. When 25(OH)D levels were below 75 nmol/L, parathyroid hormone levels have been shown to increase [40]. In the large population-based National Health and Nutrition Examination Survey III, 25(OH)D levels in the range of 22.5–94 nmol/L were positively associated with bone mineral density [41]. There are no very large RCTs of supplemental vitamin D versus placebo in patients with osteoporosis.

#### 4. RCTs of effects of vitamin D supplementation on bone density

For the general population, more recent RCTs, presented herein, support the 2011 IOM recommendations of low to moderate doses of supplemental vitamin D and a lower serum 25(OH)D goal of 50 nmol/L as sufficient. In these RCTs, high daily doses (2000 IU) of supplemental vitamin D did not reduce bone loss or fractures in midlife and older men and women with baseline 25(OH)D levels of <75 nmol/L or even <50 nmol/L, indicating that a lower serum 25(OH)D goal is sufficient for bone health in the general population [11].

##### 4.1 RCTs of supplemental vitamin D versus placebo on areal bone mineral density in the general population

An ancillary study to the large VITamin D and Omega-3 Trial (VITAL) assessed effects of daily vitamin D<sub>3</sub> (cholecalciferol 2000 IU/day) versus placebo on areal bone mineral density (aBMD) in the United States [42]. VITAL investigated effects of supplemental vitamin D<sub>3</sub> and/or omega-3 fatty acids (1 g/d) versus placebo in a 2 × 2 factorial design on the primary prevention of cancer and cardiovascular disease in US men ≥50 years old and women ≥55 years old, including 5106 black participants (n = 25,871), enrolled from all 50 states [43,44]. In a subcohort of generally healthy participants from the New England region, excluding those on osteoporosis treatments or other bone active medications (n = 771; mean age ± SD = 63.8 ± 6.1 years), supplemental vitamin D<sub>3</sub> versus placebo for 2 years did not affect changes in aBMD at the spine, femoral neck, total hip, or whole body as assessed by dual X-ray absorptiometry (DXA). With a mean baseline 25(OH)D of 69.1 nmol/L, these participants may have had vitamin

D levels sufficient for bone health prior to the start of the RCT [42]. There was no effect modification of supplemental vitamin D<sub>3</sub> versus placebo on bone density when baseline total 25(OH)D levels were stratified above and below 70 nmol/L (median), 50 nmol/L, 37 nmol/L, or 30 nmol/L. Of note, only 25 participants (3.1%) in this bone density subcohort had baseline 25(OH)D levels of <30 nmol/L, consistent with the US National Health and Nutrition Examination Survey data from 2011 to 14 reporting 2.9% of the population ≥60 years having 25(OH)D levels <30 nmol/L [45].

The Vitamin D Assessment (ViDA) trial was conducted in community-dwelling older adults in New Zealand and had a lower mean baseline 25(OH)D level of ~55 nmol/L. In this RCT, bolus dosing of supplemental vitamin D (100,000 IU/month) versus placebo in 452 participants for 2 years resulted in a slight attenuation of bone loss at the femoral neck and total hip by 0.5% but had no effect on aBMD at the lumbar spine or total body [46]. In subgroup analyses, vitamin D<sub>3</sub> supplementation prevented bone loss at the spine and femoral neck among participants with very low baseline 25(OH)D levels (≤30 nmol/L). There were no differences in changes in aBMD in participants with higher baseline 25(OH)D levels.

In the Vitamin D and Cardiovascular Risk study (VICTORY), 305 women aged 60–70 years old with baseline 25(OH)D of 33.8 nmol/L from Aberdeen, Scotland, were randomized to vitamin D 400 IU daily, vitamin D 1000 units daily, or placebo. Vitamin D supplementation of 1000 IU/day for 1 year prevented bone loss at the total hip, compared with 400 IU/day or placebo [47]. There were no differences in changes in lumbar spine BMD among the treatment groups, except in participants with baseline 25(OH)D levels of ≤30 nmol/L, in whom there was a very small benefit [48].

Other RCTs have not found a benefit of supplemental vitamin D on bone density using different regimens, even in individuals with low vitamin D levels. In an RCT in 230 postmenopausal women in Madison, Wisconsin, with baseline 25(OH)D levels of 52.5 nmol/L, supplementation with two regimens of vitamin D (bolus 50,000 IU twice per month or 800 IU/day) versus placebo did not affect aBMD [49]. In an RCT of several doses of supplemental vitamin D up to 4800 IU/day and placebo in 273 older US women with baseline total 25(OH)D levels ≤50 nmol/L, there were also no differences in percent changes in aBMD. In this RCT, changes in aBMD were not associated with baseline total 25(OH)D levels [50]. Another RCT of three different bolus doses of vitamin D<sub>3</sub> supplements (12,000 IU/month, 24,000 IU/month, or 48,000 IU/month; no placebo) in 379 older UK adults also did not find any differences in aBMD changes over 1 year, and there was no effect modification by baseline total 25(OH)D levels [51].

## 4.2 RCTs of supplemental vitamin D versus placebo on areal bone mineral density in the general population: a look at free vitamin D levels

In contrast to the studies in New Zealand and Aberdeen, results from the VITAL study did not show any benefit of supplemental vitamin D on bone density or find a baseline 25(OH)D threshold that resulted in a benefit. These inconsistencies may stem from the use of serum total 25(OH)D level as a biomarker for vitamin D status. As vitamin D is primarily bound to vitamin D-binding protein in the circulation, it may be the free 25(OH)D concentrations that predominantly exert the biological effects on bone [52–56].

At present, research studies investigating the relationship between free 25(OH)D levels and the effects of supplemental vitamin D on aBMD are limited. Small RCTs of supplemental vitamin D have not found an association between changes in aBMD and baseline-free 25(OH)D levels [50,51]. The larger VITAL study in 771 adults found that baseline-free 25(OH)D levels, measured using an ELISA assay (Future Diagnostics Solutions BV, Netherlands), may better predict improvements in aBMD than total 25(OH)D levels. Among VITAL participants with baseline-free 25(OH)D levels below the median (14.2 pmol/L), there was a small benefit for vitamin D supplementation versus placebo on changes in aBMD at the spine (0.75% vs. 0.00%,  $P = .04$ ) and total hip (−0.42% vs. −0.98%,  $P = .04$ ) [42]. Whether baseline-free 25(OH)D levels identify individuals more likely to benefit from vitamin D supplementation on fracture outcomes warrants further study.

## 4.3 RCTs of supplemental vitamin D versus placebo on areal bone mineral density in high-risk populations

A larger benefit may be found in those at high fracture risk, compared with the general adult population. In an RCT performed in the Netherlands in 348 elderly women at high fracture risk (mean age 80 years; baseline 25(OH)D of ~26.0 nmol/L), 400 IU/d of vitamin D<sub>3</sub>, compared with placebo, resulted in an increase in femoral neck aBMD by 1.9% over 2 years [57]. The New Dietary Strategies Addressing the Specific Needs of the Elderly Population for Healthy Aging in Europe (NU-AGE) study, however, found that vitamin D<sub>3</sub> supplementation (400 IU/day), along with a Mediterranean diet, for 1 year had no effect on aBMD in older men and women but, in exploratory analyses, attenuated femoral neck bone loss in those with osteoporosis [58]. In a study in 150

elderly UK women who had hip fractures, vitamin D<sub>3</sub> supplementation, administered as a single bolus injection of 300,000 IU of vitamin D<sub>2</sub> (with or without 1 g/day of elemental calcium) or vitamin D<sub>3</sub> 800 IU/day with 1 g/day of elemental calcium, versus placebo also resulted in 1-year improvements in aBMD at the femoral neck by 2.7% and at the total hip by 3.5% [59].

## 4.4 RCTs of supplemental vitamin D versus placebo on volumetric bone mineral density

While areal BMD by DXA is clinically used for diagnosis of osteoporosis and fracture risk predication, there are limitations including measurement variations due to bone size, degenerative changes, increased body fat, and marrow fat [60–62]. Peripheral quantitative computed tomography (pQCT) can measure volumetric BMD that is independent of bone size and separately assesses cortical and trabecular components of bone. In VITAL, vitamin D<sub>3</sub> supplementation, compared with placebo, did not affect total, trabecular, or cortical vBMD, cortical thickness, or bone strength measures at the radius or tibia [42]. An RCT from Calgary, Canada, found that high doses (4000 IU/day or 10,000 IU/day) versus a low dose of vitamin D (400 IU/day) for 3 years in 311 healthy adults without osteoporosis resulted in loss of vBMD at the radius and tibia; this was not a placebo-controlled trial. This study raised concerns that high doses of supplemental vitamin D may adversely affect bone structure [63].

## 5. RCTs of effects of vitamin D supplementation on fracture risk

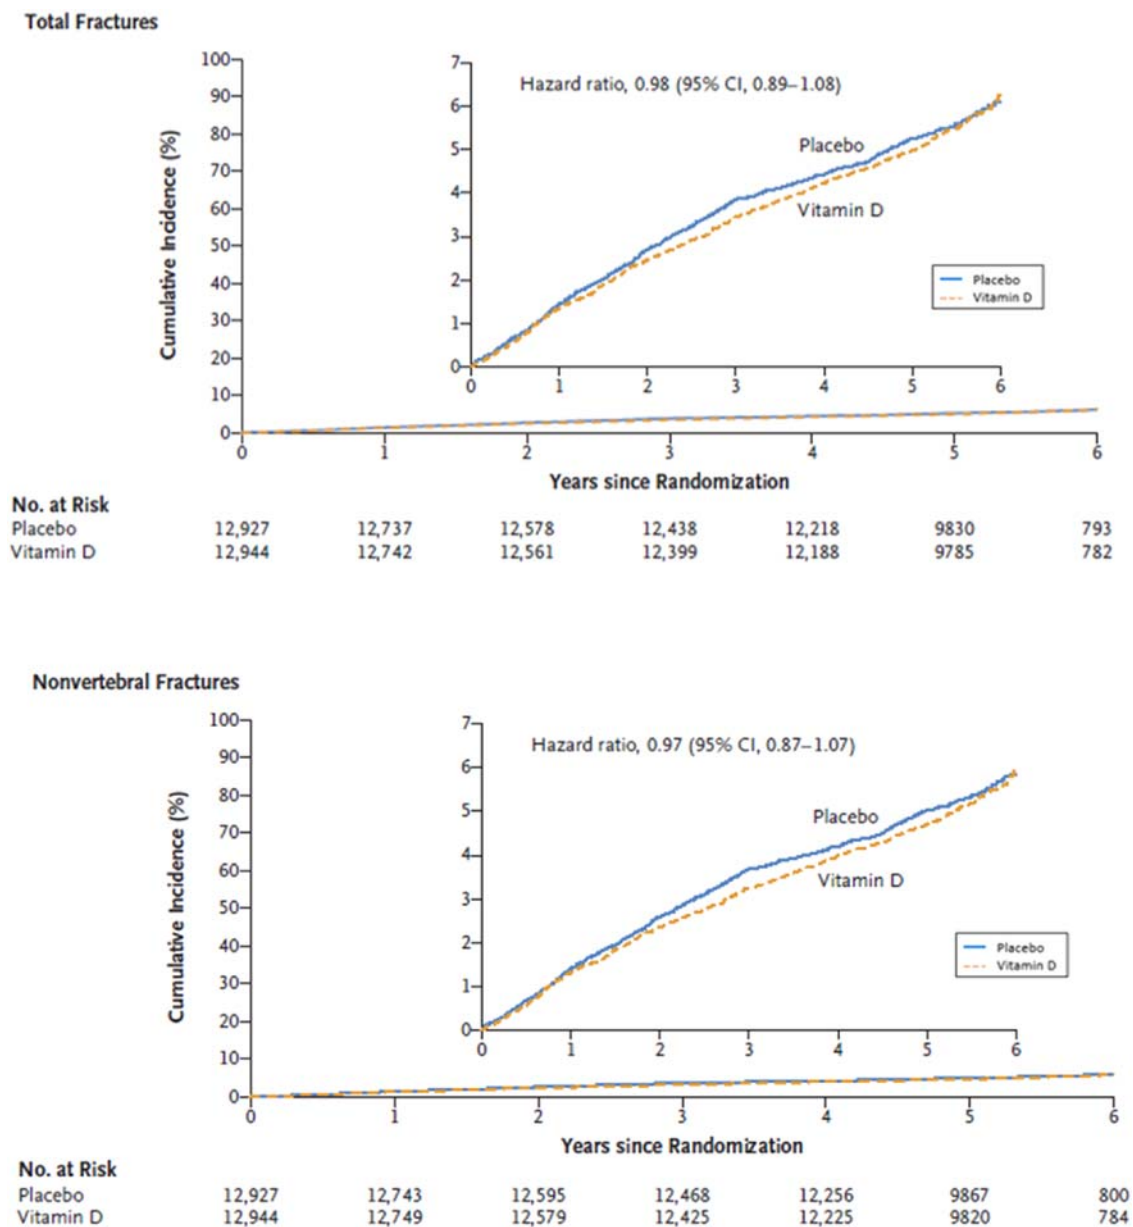

### 5.1 RCTs of supplemental vitamin D versus placebo on incident fractures in the general population

RCTs investigating effects of supplemental vitamin D on fracture risk have mostly shown no benefit, a few with benefit, and even some demonstrating potential harm [9–16]. These inconsistent findings may be due to several factors including use of bolus dosing [12,14], coadministration of vitamin D with calcium supplements [33,64], short study duration, small sample sizes, and/or differences in fracture risk of participants [10]. These variables also make metaanalyses more difficult to interpret. Table 72.1 summarizes many of these RCTs.

More recent RCTs have tested higher daily doses ( $\geq 2000$  IU/day) of vitamin D<sub>3</sub> supplementation alone (without coadministration with calcium) and have not

found a benefit for fracture outcomes. VITAL is the largest study of supplemental vitamin D<sub>3</sub> versus placebo on incident fracture risk. In VITAL, daily supplementation of vitamin D<sub>3</sub> (2000 IU/day) versus placebo did not reduce the risk of incident total (HR, 0.98; 95% CI, 0.89–1.08), nonvertebral (HR, 0.97; 95% CI, 0.87–1.07), and hip (HR, 1.01; 95% CI, 0.70–1.47) fractures in 25,871 US men aged  $\geq 50$  and women aged  $\geq 55$  years (mean  $\pm$  SD age  $67.1 \pm 7.1$ ) with a median follow-up of 5.3 years [11] (Fig. 72.1). When skull/facial, digits, peri-prosthetic, and pathological fractures were excluded, supplemental vitamin D still had no significant effect

on all outcomes. Fractures were centrally adjudicated by medical record review. Total 25(OH)D levels were measured by liquid chromatography tandem mass spectrometry (Quest Diagnostics, CA) and calibrated to Centers for Disease Control and Prevention (CDC) standards. In the active vitamin D group, mean 25(OH)D levels increased from 72.9 nmol/L to 102.8 nmol/L ( $P < .001$ ,  $n = 1347$ ) after 2 years with no significant changes in the placebo group. In exploratory analyses, there was no effect modification by age, sex, race/ethnicity, or baseline 25(OH)D levels ( $<30$ ,  $<50$ ,  $<75$ , or  $\geq 125$  nmol/L). There was limited

**FIGURE 72.1** Incident fractures in the vitamin D and placebo groups in 25,871 VITAL participants. Participants were followed for a median of 5.3 years. Incident fractures were centrally adjudicated by medical record review. Intention-to-treat analyses were performed using Cox regression models, controlled for age, sex, race, and n-3 fatty acid intervention. The insets display these same data with an enlarged y axis [11].

FIGURE 72.1 Cont'd

power to test the effects of supplemental vitamin D on fractures among participants with 25(OH)D levels  $<30$  nmol/L and low power in participants with history of fragility fracture or on osteoporosis treatments at baseline. Results did not change in a sensitivity analysis for adherence, and in exploratory analyses, no latency effects were observed by excluding the first couple of years of the intervention. Subgroup and post hoc analyses in VITAL were not able to identify any cohort of participants for whom supplemental vitamin D had a fracture benefit. Overall, these results only apply to healthy adults not preselected for osteoporosis, severe vitamin D deficiency, or gastric and intestinal conditions that may interfere with vitamin D absorption. This study calls into question the need for vitamin D supplementation for bone health in the general population, and small-to-moderate amounts of vitamin D through diet and/or sunlight may be sufficient in the United States.

The DO-HEALTH study investigated supplemental vitamin D of 2000 IU/day alone or in combination with omega-3 fatty acids (1000 mg/day) and a strength-training exercise program on nonvertebral fractures in 2157 European adults  $\geq 70$  year old (mean age  $74.9 \pm 4.4$ ). After a median follow-up of 3 years, there was also no effect of vitamin D supplementation on nonvertebral fracture risk in this older European cohort [10].

There has been increasing concern that very high levels of 25(OH)D may actually increase fracture risk, particularly among frail older adults, as supported by

RCTs that administered massive boluses of vitamin D supplementation. An annual oral dose of 500,000 IU of cholecalciferol in community-dwelling women 70 years or older resulted in an increased risk of fractures (RR, 1.26; 95% CI, 1.00–1.59) and an increased risk of falls (RR, 1.15; 95% CI, 1.02–1.30), particularly within 3 months of dosing [16]. Another study in men and women 75 years and older found that an annual intramuscular injection of 300,000 IU of ergocalciferol versus placebo resulted in a 49% increase in femoral fractures [15]. Of note, the baseline 25(OH)D level of this study was unusually high at 141.3 nmol/L. Similar to other endocrine feedback loops, high doses of vitamin D and 25(OH)D levels may become counterproductive by stimulating 24-hydroxylase to inactivate 1,25(OH)<sub>2</sub>D and increasing fibroblast growth factor-23 levels, which, in turn, may suppress 1 $\alpha$ -hydroxylase and downregulate activation of vitamin D [65]. Thus, the modulatory effects of vitamin D boluses may be reduced for weeks. The role of free 25(OH)D levels has not been explored in these RCTs of supplemental vitamin D versus placebo on fracture outcomes.

## 5.2 RCTs of supplemental vitamin D versus placebo on fractures in high-risk populations

There has been interest in assessing whether supplemental vitamin D versus placebo may have benefits on fracture outcomes in those with low baseline 25(OH)D

levels. As RCTs investigating the effects of supplemental vitamin D on fractures need to be large, it is difficult, and likely unethical, to select a study population with very low vitamin D levels. In a few RCTs with low baseline 25(OH)D levels, including the DO-HEALTH Trial, vitamin D supplementation did not reduce fracture risk. The ViDA study in New Zealand investigated the effects of vitamin D<sub>3</sub> 100,000 IU/month in 5110 women and men aged 50–84 years with a mean baseline 25(OH)D level of 63 nmol/L and also did not find effects on nonvertebral fractures or falls over 3.3 years [14]. Vitamin D<sub>3</sub> supplementation also did not reduce fractures in ViDA participants with baseline 25(OH)D levels <50 nmol/L (n = 1270). Similarly, in subgroup analysis of the large VITAL trial, 2161 participants had baseline 25(OH)D levels of <50 nmol/L, but no effect of supplemental vitamin D was seen in this subgroup. However, Trivedi et al. found that oral vitamin D<sub>3</sub> 100,000 IU every 4 months with 5 years of follow-up resulted in a reduction in the rate of first fracture by 22% (95% CI, 0.61–0.99) and first fracture of hip/wrist/vertebra by 33% (95% CI, 0.48–0.93) in women and men aged 65–85 years [12]. In this RCT, the 4-year follow-up 25(OH)D level was  $52.5 \pm 21.3$  nmol/L in the placebo group and  $75 \pm 20.8$  nmol/L in the vitamin D<sub>3</sub> treatment group [12].

Some RCTs have tried to target populations at higher fracture risk by older age or those living in residential communities, and these results have been disappointing. Sanders et al. specifically studied older women ( $\geq 70$  years old) with high hip fracture risk, based on history of maternal hip fracture, past fracture, or recurrent falls [16]. However, the use of annual oral dose of 500,000 IU of cholecalciferol, as mentioned before, resulted in more fractures. Law et al. investigated the use of oral vitamin D<sub>3</sub> at 100,000 IU every 3 months in elderly women and men in residential facilities (mean age 85 years old) and found no effect on nonvertebral fractures or falls after only 10 months [13]. In a Dutch study, supplemental vitamin D of 400 IU/day versus placebo in elderly adults (mean  $\pm$  SD age  $80 \pm 6$ ) from both independent and residential facilities also had no effect on hip or peripheral fractures over 3.5 years of follow-up [9]. Overall, RCTs have not suggested a strong role for supplemental vitamin D alone, without coadministration of calcium, on fracture reduction, even in high-risk populations.

### 5.3 RCTs of the effects of supplemental calcium and vitamin D on risk of fractures

The RCTs of vitamin D supplements with calcium on fracture risk have also been inconsistent [33,34,66–71]. In the Women's Health Initiative, supplemental calcium

(1000 mg/d) plus vitamin D (400 IU/d) in 36,282 postmenopausal women was not associated with a significant reduction in hip fracture risk. Subgroup analyses indicated that in women who adhered to the combined calcium and vitamin D intervention or did not take calcium and vitamin D supplements at baseline, hip fracture risk was reduced by 29% and 38%, respectively [33,34]. In contrast, in a subcohort (n = 3432) of the Osteoporosis Risk Factor and Prevention (OSTPRE) Study, an RCT of daily vitamin D (800 IU/d) and calcium (1000 mg/d) versus placebo in postmenopausal women with 3 years of follow-up did not find any effect of calcium and vitamin D supplementation on fracture incidence [67]. In VITAL, in a post hoc analysis, there was no effect modification of supplemental vitamin D versus placebo on fracture incidence in the 20% of the participants (n = 5166) who took calcium supplements ( $\leq 1200$  mg/d) at baseline or those adherent to the vitamin D intervention. Findings from these studies suggest that calcium and vitamin D supplementation do not reduce fracture risk in the general population (Table 72.2).

## 6. Implications for clinical practice

Vitamin D plays an important role in absorption of calcium, and extremely low levels of vitamin D are associated with rickets in children and osteomalacia in adults. Results from the recent large placebo-controlled RCTs indicate that in healthy midlife and older adults, high doses of vitamin D (2000 IU/day) do not provide an added benefit for fracture risk. In the United States, there may be sufficient vitamin D for bone health through diet and incidental sun exposure; the baseline 25(OH)D levels in VITAL may reflect decades of fortification of milk, some cereals, and other sources of vitamin D.

For individuals with high fracture risk with known osteoporosis or low bone density, it is reasonable and safe to treat patients with vitamin D supplements along with adequate calcium intake. However, pharmacologic therapies, including alendronate, zoledronate, denosumab, teriparatide, abaloparatide, and romosozumab, reduce fracture risk by 40%–85% and are far more effective than vitamin D and calcium supplementation alone [72–74]. Furthermore, many of these large RCTs included calcium and vitamin D supplementation in both the pharmacologic osteoporosis treatment and placebo arms. Adequate calcium and vitamin D intakes are also necessary to prevent complications of hypocalcemia with strong antiresorptive medications, particularly zoledronate and denosumab. In addition to those with osteoporosis, vitamin D supplementation is reasonable

**TABLE 72.2** Large randomized controlled trials of supplemental vitamin D and calcium on fractures.

Study	Participants	Intervention	Duration	25(OH)D levels	Key findings
Chapuy et al. [64]	Women in nursing homes or apartments for elderly, mean age $84 \pm 6$ years ( $n = 3270$ )	1200 mg of calcium and 800 IU of vitamin D <sub>3</sub> daily	18 months	Baseline: $39.9 \pm 27.5$ nmol/L in vitamin D <sub>3</sub> -calcium treatment group, $32.4 \pm 22.5$ nmol/L in placebo group Follow-up (18 months): $104.8 \pm 22.5$ nmol/L in vitamin D <sub>3</sub> -calcium treatment group, $27.5 \pm 17.5$ nmol/L in placebo group	Reduced risk of hip fractures by 43%, nonvertebral fractures by 32%.
Chapuy et al. [68]	Institutionalized women, mean age $85.2 \pm 7.1$ ( $n = 583$ )	1200 mg of calcium and 800 IU vitamin D <sub>3</sub> daily or placebo	2 years	Baseline: $21.2 \pm 13.2$ nmol/L in the intervention group, $22.7 \pm 17.2$ nmol/L in the placebo group	No effect on hip fracture.
Larsen et al. [69]	Northern Europe: Community-dwelling adults $\geq 66$ years old, median age 74 (range, 65–103) ( $n = 9605$ )	Oral calcium 1000 mg and vitamin D <sub>3</sub> 400 IU daily or control	3 years	Baseline: $37 \pm 19$ nmol/L in the intervention group, $33 \pm 19$ nmol/L in the control group Follow-up: $47 \pm 20$ nmol/L in the intervention group, $38 \pm 18$ nmol/L in the control group at 24 months	Reduced major osteoporotic fracture incidence rate by 16%.
Grant et al. [70], RECORD	United Kingdom: women and men $\geq 70$ years old, mean age of $77 \pm 6$ , with history of fracture ( $n = 5292$ )	Oral calcium 500 mg and vitamin D <sub>3</sub> 400 IU twice daily (800 IU/d), or placebo	3 years	Baseline: $37.9 \pm 16.2$ nmol/L Follow-up (1 year): Rose by $24.0 \pm 17.2$ nmol/L in combination treatment group, rose by $7.7 \pm 18.0$ nmol/L in placebo group	No effect on low-trauma, total or hip fractures.
Porthouse et al. [71]	England: women $\geq 70$ years old, mean age $77 \pm 5$ , with $\geq 1$ risk factors for hip fracture ( $n = 3314$ )	Oral calcium 500 mg and vitamin D <sub>3</sub> 400 IU twice daily (total 800 IU/d) or control	25 months (median)		No effect on hip or clinical fractures.
Jackson et al. [33], Prentice et al. [34], Women's health Initiative [33,34]	United States: women aged 50–79, mean $\pm$ SD age $62.4 \pm 7.0$ ( $n = 36,282$ )	Oral calcium 500 mg with vitamin D <sub>3</sub> 200 IU twice daily (400 IU/day) or placebo	7.0 years (mean)	Baseline: $46.0 \pm 22.6$ nmol/L among participants with previous hip fracture (in nested case-control assessment), $48.4 \pm 23.5$ nmol/L in control group Follow-up: 28% higher in active calcium + vitamin D <sub>3</sub> group compared with placebo group	No effect on hip, clinical vertebral, wrist, or total fractures. Reduced risk of hip fracture by 29% in adherent participants. Reduced risk of hip fracture by 38% in participants not on calcium and vitamin D <sub>3</sub> supplements at baseline ( $n = 15,302$ ).
Salovaara et al. [67], OSTPRE	Finland: women aged 65–71 years, mean $\pm$ SD age $67.4 \pm 1.9$ ( $n = 3432$ )	Oral calcium 500 mg and vitamin D <sub>3</sub> 400 IU twice daily (800 IU/d) or control	3 years (mean)	Baseline: $50.0 \pm 18.7$ nmol/L (mean) in the intervention group, $49.1 \pm 17.7$ nmol/L in the control group Follow-up: $74.6 \pm 21.9$ nmol/L in the intervention group, $55.9 \pm 21.9$ nmol/L in the control group	No effect on total, nonvertebral, clinical vertebral, osteoporotic, or wrist fractures.

in patients with very low 25(OH)D levels, limited sun exposure, and malabsorption or related gastrointestinal disorders.

## 7. Conclusion

Recommendations for vitamin D for the promotion of bone health and prevention of fractures continue to be studied and debated. Recent findings from large RCTs have challenged the long-standing notion that high doses of vitamin D reduce fractures in the general population. Supplemental vitamin D (2000 IU/d), compared with placebo, did not reduce fracture risk in 25,871 healthy middle-aged and older US adults over a median of 5.3 years of follow-up in VITAL [11]. Smaller doses of vitamin D may be sufficient for bone health. Furthermore, RCTs have had more difficulty finding therapeutic thresholds. The large VITAL study, which measured baseline 25(OH)D levels in 16,757 participants, did not show a benefit of high-dose supplemental vitamin D (2000 IU/d) on fracture reduction at clinically relevant thresholds. Current thresholds for bone are not fully evidence-based and may need to be reevaluated in the context of these data.

For patients with osteoporosis at high risk of fractures, pharmacological therapies can markedly reduce fracture risk. The findings in the VITAL study should not be extrapolated to individuals with low bone mass or osteoporosis. The statistical power in VITAL for effects of supplemental vitamin D versus placebo on incident fractures in the participants who had fragility fractures or were on osteoporosis medications at baseline was low. Supplementation with vitamin D and calcium in patients with low bone mass, osteoporosis, or on osteoporosis medications is safe, and we continue to recommend this for these patients.

Overall, widespread screening of serum 25(OH)D levels in generally healthy midlife and older adults should be curtailed as it is likely unnecessary for bone health outcomes. Measurement of 25(OH)D levels continues to be useful in patients with low bone mass or osteoporosis in the evaluation of secondary causes of osteoporosis such as hyperparathyroidism or malabsorption. Other studies in the large VITAL cohort have shown a few select patient populations who may benefit from vitamin D supplementation. Although supplemental vitamin D (2000 IU/d) did not decrease cancer incidence or a composite of cardiovascular outcomes in the overall VITAL cohort, in a subgroup analysis, it did decrease cancer mortality by 25% after a latency period [44,75] and autoimmune diseases by 22% [76]. Ongoing studies are investigating effects of supplemental vitamin D on infections, lung disease, and COVID among others.

## 8. Summary points

- Although vitamin D supplements are widely used in the general population to benefit bone health, findings from RCTs have been inconsistent.
- Recent large RCTs have generally found no benefits of high daily doses of supplemental vitamin D (without coadministration of calcium) on areal bone mineral density.
- Recent RCTs have also not supported the use of supplemental vitamin D to reduce incident fractures in generally healthy, community-dwelling adults in the United States and globally.
- These findings do not apply to adults with severe vitamin D deficiency, low bone density or osteoporosis, or elders living in residential communities.

The VITAL ancillary studies, *Effects of Supplemental Vitamin D on Bone Health Outcomes in Women and Men in the VITamin D and Omega-3 Trial (VITAL)*, *Supplemental Vitamin D and Incident Fractures in Midlife and Older Adults*, and *The clinician's guide to prevention and treatment of osteoporosis*, are supported by grants (R01 AR060574, R01 AR070854, and R01 AR059775, to Dr. LeBoff) from the National Institute of Arthritis and Musculoskeletal and Skin Diseases. The VITAL parent trial is supported by grants (U01 CA138962, R01 CA138962, and R01AT011729, to Drs. Manson and Buring) from the National Cancer Institute, the National Heart, Lung, and Blood Institute, the Office of Dietary Supplements, the National Institute of Neurological Disorders and Stroke, and the National Center for Complementary and Integrative Health.

The ancillary study *COSMOS: Effects on Falls and Physical Performance* is supported by grant R01AG071611 from the National Institute on Aging. The COSMOS parent trial is supported by Mars Edge and Pfizer (now GSK) Consumer Healthcare. The ancillary study *COSMOS: Effects on Falls and Physical Performance* was also supported by Grant Number 1UL1TR001102 and 1UL1TR002541-01. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Center For Research Resources, the National Center for Advancing Translational Science, or the National Institutes of Health.

# Calcifediol as a therapeutic

John S. Adams<sup>1</sup>, Albert Shieh<sup>2</sup> and Charles W. Bishop<sup>3</sup>

<sup>1</sup>Departments of Orthopaedic Surgery, Medicine and Molecular, Cell and Developmental Biology, UCLA, Los Angeles, CA, United States <sup>2</sup>Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA, United States

<sup>3</sup>Renal Division, OPKO Health, Inc, Miami, FL, United States

## OBJECTIVES

- To highlight the recent, novel uses of calcifediol (25-hydroxyvitamin D<sub>3</sub>) as an oral therapeutic agent to safely and effectively raise serum levels of 25-hydroxyvitamin D and, thereby, treat (i) secondary hyperparathyroidism in chronic kidney disease complicated by vitamin D insufficiency and (ii) respiratory microbial diseases including COVID-19.

## 1. Introduction

Calcifediol or 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>) is at the apex of the vitamin D metabolic pathway. It is the major circulating form of vitamin D and substrate for the two principal metabolites of vitamin D<sub>3</sub>, namely 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub> or calcitriol) and 24,25-dihydroxyvitamin D<sub>3</sub> (24,25(OH)<sub>2</sub>D<sub>3</sub>), but is infrequently considered for its therapeutic potential. Here, we will consider the recent data supporting the use of calcifediol and, in particular, extended-release calcifediol (ERC) in treating: (1) vitamin D insufficiency (VDI), defined by a total serum total 25-hydroxyvitamin D (25(OH)D) level of <20 ng/mL (50 nmol/L) or <30 ng/mL (75 nmol/L); (2) secondary hyperparathyroidism (SHPT), especially in the setting of chronic kidney disease (CKD); and (3) microbial infections associated with deficient innate and adaptive immune responses to the offending microbe. The mechanism of action of

calcifediol revolves around both traditional endocrine actions of calcitriol and nontraditional production of intracrine calcitriol.

As displayed in Table 73.1, traditional endocrine and nontraditional intracrine mechanisms of action of calcifediol share a common enzymatic target (25-hydroxyvitamin D-1 $\alpha$ -hydroxylase or CYP27B1), active metabolite (calcitriol), and tissue-based receptor (vitamin D receptor or VDR), but differ in most other respects. This includes the cell types that harbor CYP27B1. The endocrine-acting CYP27B1 is concentrated in epithelial cells of the proximal renal tubule [1,2], while the intracrine-acting CYP27B1 is expressed outside the kidney, for example in parathyroid cells and in activated cells of the innate immune system ([3]; see Chapter 9). The preferred substrates for the renal CYP27B1 are the two most abundant, 25-hydroxylated, circulating metabolites of vitamin D. The first is 25(OH)D<sub>3</sub> which is largely synthesized in the liver by the CYP2R1 [4]. The second is 24,25(OH)<sub>2</sub>D<sub>3</sub>, the product of the CYP24A1, the vitamin D-specific catabolic enzyme [5]. Hydroxylation at the C-24 position initiates side chain cleavage of the molecule and its eventual catabolism to nonbiologically forms (reviewed in Jones et al. [6]; see Chapter 5).

The CYP24A1 enzyme is highly concentrated on the inner mitochondrial membrane of cells of the proximal renal tubule alongside CYP27B1, where its expression is more robust than that of the CYP27B1 (see Chapters 5 and 8). CYP24A1 is not as substrate limited or tightly regulated as CYP27B1 [6]. Consequently, in the disease free state, CYP24A1 can easily “out compete” CYP27B1 for the same substrates, leading to their catabolic deactivation. CYP24A1 is widely distributed among almost all tissues and cells of the body that express the VDR.

**TABLE 73.1** The function of the 25(OH)D<sub>3</sub> (calcifediol)/1,25(OH)<sub>2</sub>D<sub>3</sub> (calcitriol) axis in its traditional endocrine action compared to its non-traditional intracrine action.

Function	Endocrine action	Intracrine action
Cell	Proximal renal tubular epithelial cell	Target cell (e.g., macrophage)
Enzyme	CYP27B1	CYP27B1
Substrate (optimal range)	25(OH)D <sub>3</sub> (50–75 nM)	25(OH) <sub>3</sub> D (125–250 nM)
Mode of 25(OH)D <sub>3</sub> delivery	Megalin-bound DBP	Free 25(OH)D <sub>3</sub>
Source of 25(OH)D <sub>3</sub>	Urine	Serum
Substrate concentrated	Yes	No
Competition for substrate	CYP24A1 (robust)	Alternatively spliced CYP24A1
Enzymatic products	1,24,25(OH) <sub>3</sub> D <sub>3</sub> > 1,25(OH) <sub>2</sub> D <sub>3</sub>	1,25(OH) <sub>2</sub> D <sub>3</sub> > 1,24,25(OH) <sub>3</sub> D <sub>3</sub>
Major stimulator	PTH	Tissue-specific cytokines
Other major regulator	FGF-23 (inhibitor)	Toll-like receptor activation
1,25(OH) <sub>2</sub> D <sub>3</sub> target	VDR	VDR
Regulation target	Calcium/Phosphate/PTH axis	Cell-specific, VDR-driven responses

Regardless of the tissue or cell, in normal physiology the *CYP24A1* is the most VDR-responsive human gene; it contains powerful 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D)-VDR-activatable enhancer elements [7]. As such, upregulation of expression of the *CYP24A1* gene by 1,25(OH)<sub>2</sub>D is considered a means of limiting the formation and export of active, VDR-interacting hormone by that cell [7]. By contrast, unactivated innate immune cells do not constitutively express the VDR or *CYP24A1* (see Chapter 94). Even after activation by antigens and/or cytokines, the 24-hydroxylating activity in such cells is limited by the production of an alternatively spliced, amino-terminally truncated, nonbiologically active isoform of the *CYP24A1* missing its N-terminal mitochondrial targeting sequence [8,9]. This is the reason why patients with macrophage proliferating, granuloma-forming diseases like sarcoidosis or tuberculosis where the *CYP27B1* is not counterbalanced by *CYP24A1* activity, are extremely sensitive to increases in the serum 25(OH)D level and subsequent development of 1,25(OH)<sub>2</sub>D-driven hypercalciuria and/or hypercalcemia [10].

Owing to the differences in cells containing *CYP27B1*, other salient differences reside between the endocrine- and intracrine-acting pathways for 25(OH)D<sub>3</sub> (Table 73.1). Prime among them is the means by which substrate 25(OH)D<sub>3</sub> or 24,25(OH)<sub>2</sub>D<sub>3</sub> gains access to the metabolic machinery in the cell bearing the *CYP27B1*. While the source of the substrate is the same, circulating 25(OH)D<sub>3</sub> and 24,25(OH)<sub>2</sub>D<sub>3</sub> bound to the serum vitamin D binding protein (DBP), and to a lesser extent albumin, the modes of substrate delivery differ. On the

traditional, endocrine action side of the equation, 25(OH)D<sub>3</sub> and 24,25(OH)<sub>2</sub>D<sub>3</sub>, whether DBP- or albumin-bound, are largely transferred from the blood into the urine through glomerular filtration. DBP with the bound vitamin D metabolite is then reclaimed from the urine by high affinity binding and internalization by the transmembrane megalin/cubulin complex residing on the luminal membrane of the proximal tubular epithelial cell [11]. Once internalized, most of the carrier DBP and its metabolite cargo are recycled back into the venous circulation by a yet poorly understood mechanism. It is hypothesized that some of the internalized DBP-vitamin D metabolite complex is incorporated into an endolysosome whose acidic environment cleaves DBP from the metabolite [12]. From this point, it is uncertain how free substrate finds its way to *CYP27B1* or *CYP24A1*, residing side-by-side on the inner mitochondrial membrane. It is presumed that the relative level of free substrate and factors controlling the *CYP27B1*-hydroxylation reaction (e.g., substrate affinity) will determine the relative output of 1,25(OH)<sub>2</sub>D<sub>3</sub> and 1,24,25(OH)<sub>3</sub>D<sub>3</sub> from that cell. Glomerular filtration of DBP and albumin and their subsequent capture by the megalin-cubulin internalization machinery is also a mode of concentrating vitamin D metabolites at the luminal surface of the proximal tubular epithelial cell, promoting facilitated access to the *CYP27B1* and *CYP24A1* that reside in that cell. This ability of the kidney to concentrate filtered DBP-metabolite complexes coupled with the megalin-cubulin facilitated uptake of those complexes by the proximal tubular epithelial cell may also help explain why the renal *CYP27B1* can

efficiently produce  $1,25(\text{OH})_2\text{D}_3$  at relatively low levels of serum substrate  $25(\text{OH})\text{D}_3$  (50–75 nM) compared to the higher range (125–250 nM) required for the CYP27B1 located in nonrenal target tissues or the activated human innate immune cell. Chapter 7 includes a more detailed discussion of the role of DBP in vitamin D metabolism and function.

As further depicted in Table 73.1 and in contrast to the relatively complex means of substrate delivery to the kidney CYP27B1 or CYP24A1, the delivery of substrate  $25(\text{OH})\text{D}_3$  to the activated innate immune cell is reliant on the availability of free  $25(\text{OH})\text{D}_3$  in the inflammatory microenvironment. The mechanism by which free  $25(\text{OH})\text{D}_3$  is delivered from the serum to the CYP27B1 in innate immune cells (such as macrophage and dendritic cells) is unknown. Because of its relatively high affinity for DBP and lower free levels,  $24,25(\text{OH})_2\text{D}_3$  is thought to enter the innate immune cell much less easily and not compete with  $25(\text{OH})\text{D}_3$  as substrate for the CYP27B1. As mentioned above, the wildtype CYP24A1 gene and its product, the full length, unspliced CYP24A1, are not highly expressed in the nontraditional immune metabolic pathway. In comparison to what happens with the endocrine-acting CYP27B1 and CYP24A1 in the kidney, where the output of the two enzymes counterbalances one another, without a robust CYP24A1-hydroxylase pathway in innate immune cells, substrate  $25(\text{OH})\text{D}_3$  is preferentially converted to  $1,25(\text{OH})_2\text{D}_3$ . This imbalance leads to the preferred production and release of  $1,25(\text{OH})_2\text{D}_3$  into the local inflammatory microenvironment with the potential for spillover into the general circulation when the total body load of disease-activated,  $1,25(\text{OH})_2\text{D}_3$ -secreting innate immune cells is high [13]. In this case, an increase of circulating  $1,25(\text{OH})_2\text{D}_3$  above normal can occur, making the host susceptible to the traditional, endocrine action of the  $1,25(\text{OH})_2\text{D}_3$  with resultant disturbance of calcium homeostasis [14].

The traditional, endocrine vitamin D operating system governing the renal synthesis of  $1,25(\text{OH})_2\text{D}$  is tightly regulated by other circulating hormones that control CYP27B1 and CYP24A1 gene expression. These hormonal regulators gain access to proximal tubular epithelial cell through the “blood” (basolateral membrane) not the “urine” (luminal membrane) side of the cell. The two key regulators of the renal CYP27B1 are both peptide hormones, parathyroid hormone (PTH) and fibroblast growth factor (FGF23) (see Table 73.1 and Chapters 8 and 19); they remain blood bound as they are too large to be filtered through the glomerulus. PTH is the major stimulator, and FGF23 is the major inhibitor of the renal CYP27B1 and 1-hydroxylase activity. PTH release is stimulated by a decrease in the serum ionized calcium and  $1,25(\text{OH})_2\text{D}$  concentration [15] and FGF23 synthesis is stimulated by a decrease in the

glomerular filtration rate (GFR) in early renal failure [16]. This “yin-yang” means of control of CYP27B1 expression is the essence of the endocrine feedback on  $1\alpha$ -hydroxylase activity (see Chapters 8 and 9). It is the concerted interplay of the  $1,25(\text{OH})_2\text{D}$ -VDR-target gene interactions in the gut, bone, parathyroid gland, and the kidney that serve to provide optimal circulating calcium and phosphate levels required for normal skeletal homeostasis. The pathophysiological outcome of the failure of this servosystem to control  $1,25(\text{OH})_2\text{D}$  serum levels in the appropriate range and normal  $1,25(\text{OH})_2\text{D}$ -VDR-driven trans-regulation of the genes in these target tissues is dysregulated calcium homeostasis.

As discussed below in the section “Calcifediol treatment of secondary hyperparathyroidism associated with chronic kidney disease,” CKD is perhaps the best clinical example of failure of the traditional, endocrine-active vitamin D system associated with bone loss and extra-skeletal arterial calcification. The latter is the major cause of morbidity and mortality in CKD [17]. Owing to a decrease in GFR in early CKD, there is a decrease in tubular epithelial cell function, including an undesired, increased retention of filtered phosphate from the urine back into the blood. Although still unclear mechanistically, the impact of phosphate retention is sensed by osteocytes buried in the calcium-phosphate hydroxyapatite matrix of bone and triggers the release of FGF23 into the general circulation [18]. FGF23, acting as an endocrine hormone, counters CKD-driven renal tubular reabsorption of phosphate, reduces the activity of the CYP27B1 to synthesize  $1,25(\text{OH})_2\text{D}$  and increases the activity of the CYP24A1 to catabolize  $1,25(\text{OH})_2\text{D}$  [19]. The net result is a reduction in the circulating concentration and action of  $1,25(\text{OH})_2\text{D}$ . The consequence of these FGF23-driven events at the level of the renal tubule is an increase in phosphate and calcium excretion and a decrease in the circulating levels of phosphate and calcium for incorporation into the mineral matrix of bone. In response to what would appear to be a clinically insignificant drop in ionized calcium level, the calcium-sensing receptor (CASR) in parathyroid tissue is activated leading to an increase in PTH secretion into the general circulation, a persistent state of SHPT and a further loss in bone mineral content [20]. SHPT associated with CKD is usually amplified by the presence of  $25(\text{OH})\text{D}$  insufficiency [21,22], leading to reduced serum  $1,25(\text{OH})_2\text{D}$  and a compensatory increase in PTH secretion.

Medial calcification of arterial vessels is a frequent and morbid event in patients with CKD [17]. This phenotypic alteration in the arterial cell wall is thought to be a consequence of events central to the overall pathogenesis of bone disease in CKD [23]. These include SHPT, namely the disturbance in the circulating balance of phosphate and calcium directed by an elevated PTH level.

Superimposed on that is CKD-associated hyperphosphatemia-induced increase in the expression of the PIT-1 and PIT-2 sodium-dependent phosphate co-transporters in arterial vascular smooth muscle cells [24]. This event promotes phosphate uptake by subluminal vascular smooth muscle cells with their resultant trans-differentiation to an osteogenic phenotype capable of deposition of hydroxyapatite (Fukagawa and Kazama [25]; see Chapters 26 and 79).

By contrast (see Table 73.1), activated innate immune cells that express the VDR and CYP27B1 are resistant to circulating PTH signaling as these cells do not express substantial amounts of the receptor for this calciotropic hormone [26]. Instead, the *CYP27B1* gene in activated innate immune cells is responsive to locally-produced cytokines like with IFN- $\gamma$  [27,28] and microbial-derived pathogen-associated membrane patterns (PAMP) and damage-associated molecular patterns (DAMP) operating through expressed toll-like receptors (TLR) on the cell membrane and endoplasmic membrane, respectively, with activation of the TLR2/1 being the most potent stimulator of the innate immune cell CYP27B1 and 1,25(OH) $_2$ D production [29]. Activation of the human monocyte/macrophage also leads to upregulated expression of intracrine 1,25(OH) $_2$ D-VDR-driven antimicrobial peptide genes (e.g., the cathelicidin antimicrobial peptide gene [*CAMP*]) [29] and cytokines like IL-1 $\beta$  that amplify the innate immune response and activate the adaptive immune response to the offending microbe in an autocrine/paracrine mode of action [30,31] (see section “Calcifediol treatment of microbial disease to boost the human innate and adaptive immune responses” below).

## 2. Treatment of vitamin D insufficiency with calcifediol

### 2.1 Pathophysiology of endocrine vitamin D insufficiency (VDI)

The canonical endocrine function of vitamin D is to promote intestinal calcium and phosphate absorption in order to maintain normal mineral balance and bone health. In the 25(OH)D insufficient state, low serum 1,25(OH) $_2$ D and associated reduction in intestinal calcium absorption [32,33] lead to a subclinical decline in circulating calcium. The decreases in 1,25(OH) $_2$ D and calcium are detected by the parathyroid gland via the VDR and CASR, respectively, prompting a compensatory release of PTH. PTH helps to restore normal circulating levels of 1,25(OH) $_2$ D and calcium by engaging the PTH/PTHrP receptor in the proximal tubular epithelial cell of the kidney, leading to upregulation of the CYP27B1 which converts available substrate 25(OH)D

to 1,25(OH) $_2$ D. 1,25(OH) $_2$ D then acts in an endocrine fashion, traveling to the gut to increase intestinal calcium and phosphate absorption, and to bone to liberate calcium and phosphorus from the mineral (hydroxyapatite) phase of bone [26]. Based on this underlying physiology, the compensatory rise in PTH resulting from 25(OH)D insufficiency is referred to as SHPT. Indeed, PTH levels are higher at lower serum 25(OH)D levels [34]. However, the precise threshold for 25(OH)D below which PTH secretion increases is uncertain, with some experts proposing a 20 ng/mL threshold [35] and others proposing a 30 ng/mL threshold [36]. Sustained hyperparathyroidism is detrimental to bone, as it promotes bone resorption [37].

### 2.2 Advantages and disadvantages of parent vitamin D to restore vitamin D health

Supplementation with parent vitamin D is the most commonly prescribed approach to restore status [36]. Although parent vitamin D is widely available and inexpensive, it has questionable effectiveness for treating the clinical sequelae of vitamin D insufficiency (SHPT and osteomalacia) [38–40]. First, the mechanism of intestinal absorption of ingested vitamin D is complex and relatively inefficient. Vitamin D, either as cholecalciferol or ergocalciferol, is absorbed via carrier proteins that mediate intestinal uptake of cholesterol, subsequently packaged in chylomicrons, and delivered to the general circulation via the lymphatic system [41–43]. In individuals without gastrointestinal comorbidities (e.g., Crohn’s disease), on average 78%–85% of ingested vitamin D is absorbed [44,45] when administered in the nonfasting state. However, in the absence of food, and in patients with intestinal fat malabsorption, absorption of vitamin D is often compromised; in those who have celiac disease, pancreatic insufficiency, biliary cirrhosis, or who are postbariatric surgery, intestinal vitamin D absorption can be <50% [44–46]. A second limitation of parent vitamin D is that its conversion to 25(OH)D may be impaired if there are inactivating mutations of *CYP27B1*, in end-stage liver disease, obesity [47,48] or CKD [49,50], or if *CYP27B1* activity is altered by interfering medications [51].

### 2.3 Comparative advantages of using calcifediol to restore vitamin D health

Although less widely available, calcifediol has important advantages compared to parent vitamin D. First is its greater bioavailability. Calcifediol is more polar and less fat soluble than parent vitamin D; accordingly, its intestinal absorption does not require bile acids and chylomicron formation and can exceed 93% [45].

**TABLE 73.2** Randomized controlled trials comparing the effects of calcifediol versus vitamin D<sub>3</sub> on circulating levels.

Author Year (ref)	Study size (N) Study duration	Study interventions	Baseline (ng/mL)	Final 25(OH)D (ng/mL)

Once absorbed, it enters the circulation directly via the portal vein [43]. Consistent with this physiology, the bioavailability of vitamin D<sub>3</sub> was only 44.8% or 35.9% that of calcifediol when administered at doses of 20 µg/day or 140 µg/week, respectively, for 4 months [52]. The second advantage of calcifediol is that its efficacy is not affected by alterations in CYP2R1 activity.

Table 73.2 summarizes previously published data from randomized controlled trials (RCT) comparing the effects of calcifediol versus vitamin D<sub>3</sub> on circulating 25(OH)D levels. In all [52–58]) but one [59] of the listed studies, the mean baseline 25(OH)D level was low ( $\leq 20$  ng/mL). Tested doses of calcifediol ranged from 5 µg/day to 50 µg/day, and treatment durations spanned 2–12 months. In aggregate, when compared to vitamin D<sub>3</sub>, calcifediol increased serum 25(OH)D levels more quickly and to a greater extent [52–59]. Indeed, at doses of 10 µg/day or higher, calcifediol consistently raised 25(OH)D levels in patients with normal renal function to  $>30$  ng/mL [52–59], the level below which PTH may begin to increase [60]. In contrast, cholecalciferol, even at doses of 60 µg/day, may not reliably increase serum levels above this threshold [57]. The use of calcifediol at studied doses did not result in hypercalcemia.

In a review of RCTs, the mean calculated relative potency of calcifediol versus parent vitamin D<sub>3</sub> was 4.6. Notably, the relative potency of calcifediol differed depending on the vitamin D<sub>3</sub> dose. When compared to vitamin D<sub>3</sub> at lower doses ( $<25$  µg/day), the mean relative potency of calcifediol was 3.2; but, when compared to vitamin D<sub>3</sub> at higher doses ( $>50$  µg/day), the relative potency was 8.0. The authors speculated that the CYP2R1 enzyme becomes saturated more quickly at higher doses of vitamin D<sub>3</sub>, limiting its ability to generate calcifediol [51].

## 2.4 Suppression of parathyroid hormone (PTH) secretion

Although the primary objective of the above studies was to compare the effects of calcifediol versus vitamin D<sub>3</sub> on circulating 25(OH)D levels, some investigators also explored their comparative effects on circulating PTH, with some suggesting superior (or trends toward superior) PTH suppression with calcifediol [53–56]. For example, Cashman et al. found that compared to the placebo group, study participants randomized to the 7 and 20 µg/day calcifediol but not the vitamin D<sub>3</sub> groups had significantly lower serum PTH levels after

5 and 10 weeks of supplementation [53]. Similarly, Navarro-Valverde et al. demonstrated that, after 12 months of supplementation, study participants receiving calcifediol (20 µg/day, 266 µg/week, or 266 µg/2weeks) had lower PTH levels than those receiving vitamin D<sub>3</sub> (20 µg/day) [55]. Several studies revealed trends toward greater PTH reduction with calcifediol versus vitamin D<sub>3</sub>, but that difference did not reach statistical significance. For example, Bischoff-Ferrari et al. showed that over a 4-month period, PTH decreased by 18.1 pg/mL in study participants taking 20 µg/day of calcifediol versus 5.7 pg/mL in those taking 20 µg/day of vitamin D<sub>3</sub> [54]. Similarly, Vaes et al. reported that after 24 weeks of supplementation, there was a trend toward lower mean PTH levels in the calcifediol 15 µg/day treatment group (36.7 pg/mL) versus the vitamin D<sub>3</sub> 20 µg/day group (44.3 pg/mL) [56].

Plausibly, calcifediol would be superior to parent vitamin D<sub>3</sub> for suppressing PTH production. Beyond its ability to indirectly downregulate PTH secretion via the VDR and CASR (by promoting more renal 1,25(OH)<sub>2</sub>D<sub>3</sub> production and intestinal calcium absorption), calcifediol may have the capacity to directly suppress PTH production via entry into the parathyroid cell followed by its subsequent local conversion to 1,25(OH)<sub>2</sub>D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub>-VDR-mediated suppression of *PTH* expression [61–65]. Notably, none of the above studies were specifically designed or powered to test whether calcifediol is better than parent vitamin D at reducing circulating PTH levels. RCTs should specifically examine the comparative effects of calcifediol versus parent vitamin D on PTH levels in patients with 25(OH)D insufficiency and SHPT (see section “Calcifediol treatment of secondary hyperparathyroidism associated with chronic kidney disease” below).

### 3. Calcifediol treatment of secondary hyperparathyroidism associated with chronic kidney disease

#### 3.1 Pathophysiology of secondary hyperparathyroidism (SHPT)

SHPT often develops with advancing CKD in association with vitamin D insufficiency (VDI), usually defined as a serum total 25(OH)D of <30 ng/mL or 75 nmol/L. CKD afflicts 14.4% of the United States (US) adult population [66] and approximately 9.1% of the global population [67] and is driven by aging, obesity and the associated complications of hypertension and adult-onset diabetes [68]. SHPT is characterized by hypertrophy of the parathyroid glands, excessive production of PTH, and prolonged release of calcium and phosphorus from bone, leading to CKD-mineral

and bone disorder (MBD) including vascular calcification, the main cause of morbidity and mortality in CKD [69]. The majority of patients with stage 3–4 CKD develop VDI. When CKD and VDI are present in the same patient, the metabolism of the vitamin D pro-hormone (25(OH)D) to active hormone (1,25(OH)<sub>2</sub>D) by CYP27B1 in the kidney declines, causing low levels of serum 1,25(OH)<sub>2</sub>D. Declining circulating 1,25(OH)<sub>2</sub>D concentrations leading to hypocalcemia are associated with an increase in PTH secretion by the parathyroid glands [70]. In other tissues containing CYP27B1 (e.g., in disease-activated macrophages; see Table 73.1), diminished levels of 25(OH)D limit the local production of intracrine 1,25(OH)<sub>2</sub>D.

#### 3.2 Treatment of vitamin D insufficiency (VDI) in chronic kidney disease (CKD)

Supplementation with either cholecalciferol (vitamin D<sub>3</sub>) or ergocalciferol (vitamin D<sub>2</sub>) is recommended by both the Kidney/Disease Outcomes Quality Initiative (K/DOQI) and the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines [71–73] to address SHPT arising from VDI in patients with CKD. Supplementation is widely used despite a lack of expert consensus regarding the optimal dosing regimen or its effectiveness for reaching an appropriate target level of serum 25(OH)D to lower elevated PTH levels [39,73–76]. In the US and certain European countries, extended-release calcifediol (ERC) is approved to treat SHPT at a dose of 30 µg/day escalating, as needed, to 60 µg/day. In some European countries, immediate-release calcifediol (IRC) is approved to treat VDI associated with renal osteodystrophy, rickets in children, osteomalacia in adults and hypocalcemia.

Raising the serum 25(OH)D sufficiently in order to lower PTH in overweight patients with normal renal function is difficult with ergocalciferol or cholecalciferol [77], supporting the Endocrine Society’s recommended administration of two to three times more of these supplements than for patients with normal body weight [36]. VDI is highly prevalent in obese patients [78–80] consistent with the known inverse relationship between serum 25(OH)D levels and increased body weight or body mass index (BMI) [81,82]. Some studies have reported that CKD patients with severe VDI have the highest BMI values [83] and are more often morbidly obese [84].

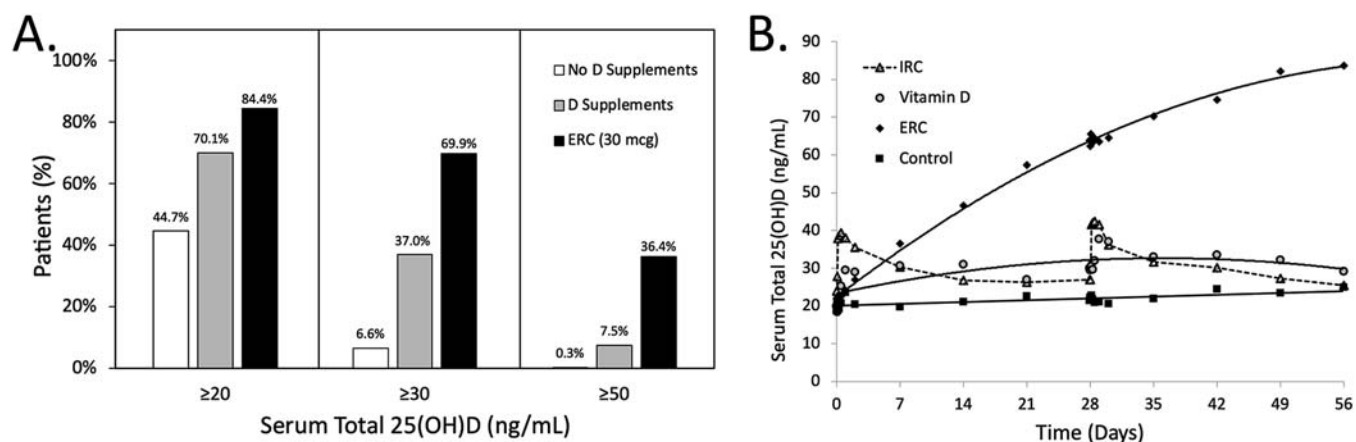

Recent evidence [39,85] has confirmed the limited effectiveness of vitamin D supplements in CKD patients, most of whom are overweight, supporting the alternative use of ERC. Data extracted from Fresenius Medical Care’s European database (EuCliD5) for 2459 adult non-dialysis CKD patients showed that only 41% had serum

25(OH)D levels of  $\geq 30$  ng/mL despite receiving standard of care treatment with parent vitamin D supplements. Only 7% had levels  $\geq 50$  ng/mL, a threshold newly identified in RCTs as required for clinically meaningful reductions in elevated PTH and serum bone turnover markers in CKD [22]. The observed negative inverse correlations of serum 25(OH)D levels with both BMI and body weight suggest that obesity can prevent routine vitamin D supplementation from raising serum 25(OH)D to targeted levels in CKD. Additional real-world data (Fig. 73.1, Panel A) have been collected in the US from a cohort of 321 adults with stage 3–4 CKD and VDI treated with cholecalciferol ( $n = 50$ ), ergocalciferol ( $n = 97$ ) or ERC ( $n = 174$ ) [85A]. Mean ( $\pm$ SE) serum 25(OH)D rose from  $19.6 \pm 8.2$  ng/mL to levels of  $\geq 30$  or  $\geq 50$  ng/mL in only 37.0% or 7.5% of patients, respectively, treated with cholecalciferol or ergocalciferol at monthly doses of  $\geq 50,000$  international units (IU) (64.7%), 14,000 to  $<50,000$  IU (23.1%) or 9000 to  $<14,000$  IU (12.2%). In contrast, 69.9% and 36.4% of patients attained these same 25(OH)D thresholds, respectively, treated with ERC at either 30 ( $n = 171$ ) or 60 ( $n = 3$ )  $\mu$ g/day.

A newly completed prospective RCT [86] evaluated the effectiveness of 8 weeks of oral treatment with cholecalciferol (300,000 IU/month;  $n = 16$ ), IRC (266  $\mu$ g/month;  $n = 15$ ) and ERC (60  $\mu$ g/day;  $n = 17$ ) versus a control group in raising serum 25(OH)D to targets of  $\geq 30$  or  $\geq 50$  ng/mL in patients with SHPT, VDI, and stages 3–4 CKD (Fig. 73.1, Panel B). Body weight was balanced among the treatment groups and mean ( $\pm$ SD) BMI was  $35.1 \pm 7.8$  kg/m<sup>2</sup>. The selected dose of oral cholecalciferol was the highest one routinely used

in adults with CKD; few clinicians would have recommended using more. The selected dose of IRC was an approved oral unit dose routinely used in Spain for CKD patients. The dose of 60  $\mu$ g/day of oral ERC was the highest approved dose and was selected to accelerate the timing under which the serum 25(OH)D targets could be attained, as normal dose titration (from 30 to 60  $\mu$ g/day) would have required a 6-month treatment period since steady-state serum levels of 25(OH)D would not have been achieved until after 3 months for any given dose. Mean ( $\pm$ SD) serum 25(OH)D gradually surpassed 50 ng/mL in 100% of subjects in the ERC group, reaching  $61.2 \pm 13.6$  ng/mL after 4 weeks of treatment and  $82.9 \pm 16.8$  ng/mL after 8 weeks. In the cholecalciferol group, mean 25(OH)D levels rose to only  $29.1 \pm 11.4$  ng/mL after 4 weeks and  $30.3 \pm 11.8$  ng/mL after 8 weeks, leaving 56% of subjects below the 30 ng/mL threshold. In the IRC group, mean 25(OH)D transiently reached the range of 37–43 ng/mL but declined below 30 ng/mL between doses. Serum 25(OH)D was unchanged in the control group. No subjects achieved serum 25(OH)D levels at or above the 50 ng/mL threshold with cholecalciferol or IRC treatment. Serum 25(OH)D levels in all groups at the end of treatment showed significant inverse relationships with body weight. ERC treatment produced 10%, 20%, and 30% reductions in plasma PTH from pretreatment baseline in 76.5%, 70.6%, and 41.2% of subjects, respectively, compared with 56.3%, 37.5%, and 25.0% for cholecalciferol treatment and 33.1%, 20.0%, and 6.7% for IRC treatment.

Data from this RCT support and extend those reported previously from an open-label RCT conducted

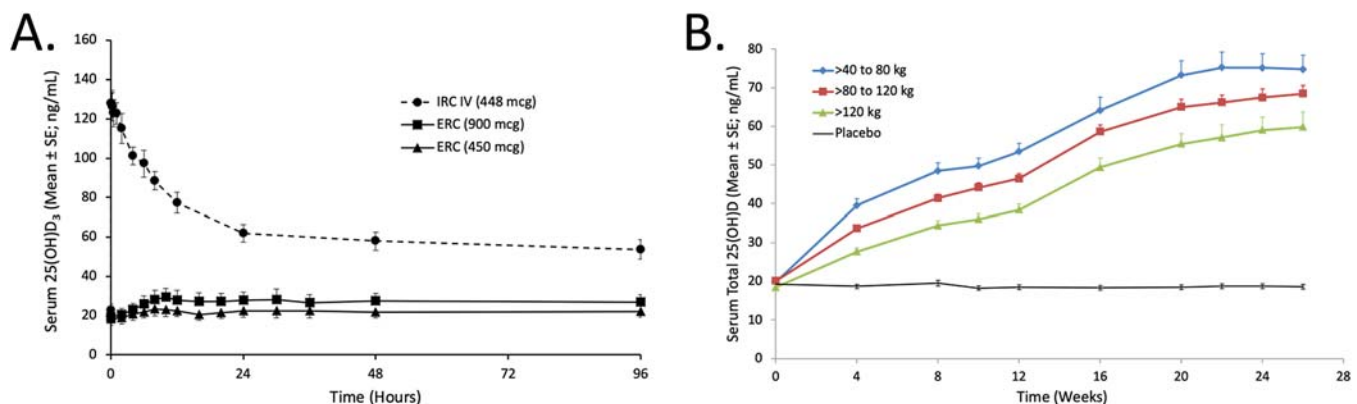

**FIGURE 73.1** Panel A shows the percentages of 321 adult chronic kidney disease (CKD) patients who achieved serum total 25-hydroxyvitamin D (25(OH)D) levels of  $\geq 20$ ,  $\geq 30$ , or  $\geq 50$  ng/mL with standard of care vitamin D repletion therapy in a real-world study in the US. These patients were treated with oral cholecalciferol (vitamin D<sub>3</sub>;  $n = 50$ ), ergocalciferol (vitamin D<sub>2</sub>;  $n = 97$ ) or extended-release calcifediol (ERC;  $n = 174$ ). Panel B depicts the mean serum total 25(OH)D levels achieved in a four-arm US RCT conducted in 69 patients with secondary hyperparathyroidism, stage 3 or 4 CKD and vitamin D insufficiency (mean 25(OH)D  $\pm$ SD  $20.6 \pm 6.6$  ng/mL) evaluating oral immediate-release calcifediol (IRC; 266  $\mu$ g/month), oral cholecalciferol (vitamin D<sub>3</sub>; 300,000 IU/month), oral ERC (60  $\mu$ g daily) versus a control group. Adapted and reprinted with permission from Ref. [86].

in a similar patient population which compared single oral ERC doses of 450 or 900  $\mu\text{g}$  to a single intravenous (IV) IRC dose of 448  $\mu\text{g}$  [87]. In that study, the 900  $\mu\text{g}$  ERC dose produced greater and more sustained PTH suppression compared to IRC despite lower bioavailability (25% vs. 100%) and 25(OH)D exposure. Mean percent reductions in PTH from baseline were minimal over the postdose period for both IRC and the lower ERC dose but reached approximately 20% for the higher ERC dose ( $P < .05$ ). As depicted in **Panel A** of [Fig. 73.2](#), the maximum concentration ( $C_{\text{max}}$ ) of serum 25(OH)D was 134 ng/mL at 0.5 h after IV administration of IRC, 33 ng/mL after 13.6 h for the higher oral ERC dose, and 25 ng/mL after 13.1 h for the lower oral ERC dose and. Subsequent studies with ERC in predialysis patients have demonstrated that PTH-lowering responses are directly proportional to the degree to which serum 25(OH)D is gradually (not suddenly) elevated, with clinically meaningful responses occurring when levels surpassed 50 ng/mL [22].

Other studies in predialysis patients have shown that oral IRC failed to produce clinically meaningful reductions in PTH ( $>30\%$  from pretreatment baseline) unless administered at doses that raised mean serum 25(OH)D to levels approaching or exceeding 100 ng/mL, the upper limit of the laboratory normal range. In one study [88], subjects were treated with oral IRC (10–50  $\mu\text{g}/\text{day}$ ) or calcium carbonate (control) for 2 years. PTH responses in the two treatment groups were reported as “comparable” and, in aggregate, PTH decreased by only 4%. Another study [89] reported that a much higher oral dose of IRC (160  $\mu\text{g}/\text{day}$ ) reduced PTH by only 6%. A third study [90] reported a mean decrease in PTH of 21%, but only at oral IRC doses of 200  $\mu\text{g}/\text{day}$  or IV doses of 500  $\mu\text{g}$  every 1–5 days. Although serum

25(OH)D levels in this third study were not reported, such high doses most certainly produced sustained levels far above 100 ng/mL. In a further study [91], 125  $\mu\text{g}$  of oral IRC administered to 29 subjects thrice weekly for 6 months yielded a mean PTH decline from 99.5 to 60.3 pg/mL ( $-39\%$ ) with serum 25(OH)D exceeding 100 ng/mL in nearly half of the subjects. Five subjects treated with IRC experienced adverse cardiovascular events, one developed hypercalcemia and one died versus none in a parallel placebo control group. Taken together, data from these previous studies and from the current study support the conclusion that gradual delivery of calcifediol in the form of ERC allows effective treatment of SHPT in CKD patients without abruptly and excessively raising serum 25(OH)D to calcemic levels.

Longer time course data for serum total 25(OH)D and plasma PTH with daily ERC treatment or placebo were examined in 429 adult patients with SHPT, stages 3–4 CKD, and VDI as a function of body weight in pooled data from two identical, concurrent prospective US RCTs [21]. Of these subjects, 356 completed the 20- to 26-week treatment period per-protocol and were included in the analysis. Enrolled subjects assigned to ERC treatment ( $n = 234$ ) ingested one 30  $\mu\text{g}$  capsule daily for 12 weeks followed by one or two capsules (30 or 60  $\mu\text{g}$ ) daily for an additional 14 weeks. Control subjects ( $n = 122$ ) received matching placebo capsules. Mean ( $\pm\text{SD}$ ) serum 25(OH)D remained unchanged with placebo treatment but rose progressively with ERC treatment to  $67.1 \pm 21.6$  ( $\pm\text{SD}$ ) ng/mL (mean of weeks 20–26). Mean serum 25(OH)D at the end of treatment was inversely related to body weight but exceeded 50 ng/mL in all weight categories ([Fig. 73.2, Panel B](#)). Side effects observed at these levels of exposure were

**FIGURE 73.2** **Panel A** compares the effects of bolus intravenous (IV) immediate-release calcifediol (IRC; 448  $\mu\text{g}$ , circles,  $n = 10$ ) and two different doses of oral extended-release calcifediol (ERC; 450  $\mu\text{g}$ , triangles,  $n = 9$  and 900  $\mu\text{g}$ , squares,  $n = 9$ ) on the mean  $\pm$  SE serum 25(OH)D in 28 adults with stage 3–4 chronic kidney disease, secondary hyperparathyroidism (SHPT) and vitamin D insufficiency (VDI; 25(OH)D  $< 30$  ng/mL). **Panel B** shows the time course of mean  $\pm$  SE serum 25OHD levels by body weight category in 356 adults with SHPT, stage 3–4 and VDI (25(OH)D  $< 30$  ng/mL) who were treated with ERC (30  $\mu\text{g}$  escalating as needed to 60  $\mu\text{g}/\text{day}$ ;  $n = 234$ ) or placebo ( $n = 122$ ) for 6 months. Reprinted with permission from Ref. [87].

similar to placebo. ERC reduced plasma PTH by at least 10% in 72% of subjects and by at least 30% in 40% of subjects, rising to 50% of subjects with longer treatment, irrespective of CKD stage or degree of obesity.

In CKD patients, oral calcitriol or another  $1\alpha$ -hydroxylated vitamin D analog is often used in place of vitamin D supplementation when PTH levels rise and remain persistently above the normal range with advancing disease. The original KDIGO clinical practice guideline for the treatment of CKD-MBD recommended this approach in patients with stage 3–4 CKD [72], consistent with the widely held view that  $1\alpha$ -hydroxylated drugs become necessary in later stages of CKD due to the loss of renal CYP27B1 activity. The more recent KDIGO guideline update [73] reversed this recommendation, suggesting instead that  $1\alpha$ -hydroxylated vitamin D hormone therapy should no longer be routinely used in nondialysis CKD due to the increased risk of hypercalcemia. The updated KDIGO guideline also highlighted the uncertain effectiveness of supplements for suppressing elevated PTH, leaving nephrologists without useful guidance on how best to treat SHPT in CKD patients. Several meta-analyses of RCTs conducted in CKD patients have shown that ergocalciferol and cholecalciferol supplementation are unreliable in achieving a serum 25(OH)D target of  $\geq 30$  ng/mL, let alone  $\geq 50$  ng/mL [39,74,75,92]. One meta-analysis [39] concluded that parent vitamin D supplementation produced such large variations in response that a precise evaluation of the true treatment effect was difficult, especially in overweight patients. When PTH rises in advancing CKD, patients are usually switched to calcitriol or another  $1\alpha$ -hydroxylated vitamin D analog with the justification that too much renal CYP27B1 has been lost, preventing the sufficient conversion of 25(OH)D to hormone. Switching, however, is inappropriate because PTH control in nondialysis patients can be accomplished by raising serum 25(OH)D safely to  $\geq 50$  ng/mL with ERC, irrespective of CKD stage and obesity, allowing for sufficient intracrine calcitriol generation extra-renal to effectively treat SHPT.

As noted previously, most CKD patients [68,93] are overweight or obese, a problem that drives disease progression through the comorbidities of type 2 diabetes and hypertension. Cholecalciferol and ergocalciferol are both fat-soluble molecules which accumulate preferentially in adipose tissue [94,95]. Both have low affinities for DBP, are poorly drawn out of adipose into circulation for hepatic activation [49,94], and are prone to in situ catabolism by the CYP24A1, the vitamin D catabolic enzyme encoded by the CYP24A1 gene that can be upregulated in earlier stages of CKD. Hepatic 25-hydroxylase activity, primarily through CYP2R1, is reduced in both obesity [47] and CKD [49,50], blunting the intended elevation of serum 25(OH)D. In contrast,

25(OH)D requires no hepatic activation, is more water soluble, and avidly binds DBP, reducing accumulation in adipose tissue and enabling its circulation to extrarenal tissues containing CYP27B1 and conversion to intracrine calcitriol [96]. Gradual delivery of 25(OH)D in the form of ERC has been shown to cause minimal suppression of extra-renal CYP27B1 and minimal upregulation of CYP24A1 [97].

Production of intracrine calcitriol, as occurs in the parathyroids and activated innate immune cells, depends on an adequate supply of 25(OH)D, fostering an ongoing dialogue about the optimum level for serum 25(OH)D in patients with stage 3–4 CKD. RCTs conducted with ERC suggest that this target should be at least 50 ng/mL [22], not 20 or 30 ng/mL endorsed by clinical practice guidelines for bone health [35,36,71], to enable the production of intracrine calcitriol and control of SHPT despite the progressive loss of renal CYP27B1 activity in advancing CKD. In fact, production of intracrine calcitriol at serum 25(OH)D levels  $\geq 50$  ng/mL has been documented in anephric patients [96] and in hemodialysis patients with intact residual kidneys [98]. As will be discussed in the next section, “Calcifediol treatment of microbial disease to boost the human innate and adaptive immune responses” and as shown in Table 73.1, the most prolific source of extra-renal  $1,25(\text{OH})_2\text{D}$  is the human monocyte-macrophage.

#### 4. Calcifediol treatment of microbial disease to boost the human innate and adaptive immune responses

##### 4.1 The concerted, serial link among calcifediol, CYP27B1, calcitriol, the vitamin D receptor (VDR), and the human immune response

This link was initially supported by a set of findings made in the early 1980s, before the actual cloning of either the human VDR or CYP27B1. First was the observation that a patient without kidneys suffering from sarcoidosis, an idiopathic, human, tissue macrophage proliferative disease primarily of the lung, could develop  $1,25(\text{OH})_2\text{D}$ -mediated hypercalcemia without any renal vitamin D-1-hydroxylating activity [99]. Second was the discovery that alveolar macrophages harvested from the lungs of patients with active sarcoidosis were capable of prolific  $1,25(\text{OH})_2\text{D}_3$  production ex vivo when exposed to physiologically relevant concentrations of 25(OH)D<sub>3</sub> in the culture medium [3]. Third were the findings that, when activated ex vivo by mitogenic lectins or Epstein–Barr virus, human peripheral mononuclear cells, including monocytes, T-lymphocytes, and B-lymphocytes,

expressed a high-affinity receptor-like molecule for  $1,25(\text{OH})_2\text{D}$  [100], later proven to be the VDR, and that when bound to  $1,25(\text{OH})_2\text{D}$  resulted in inhibition of the proliferation and biological activity of that immune cell [101].

Subsequently, other key discoveries were made that supported the immunoactions of vitamin D. These included the finding that metabolism of  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$  was the result of induced expression of the CYP27B1 by cells of the human innate immune response, including monocytes, macrophages and dendritic cells [102]. This event was supported by the finding that extra-renal overproduction of  $1,25(\text{OH})_2\text{D}$  of sufficient quantity to cause hypercalcemia in the host was observed in over 20 different granuloma-forming diseases of infectious (e.g., tuberculosis), noninfectious (e.g., silicone induced) and neoplastic (AIDS-associated B-cell lymphoma) origin [103]. In all of these diseases, the synthetic source of  $1,25(\text{OH})_2\text{D}$  was considered to be the tissue macrophage, extra-renal in nature and not bound by factors/events that normally controlled the renal  $1,25(\text{OH})_2\text{D}$  production (see Table 73.1). Hypercalcemia in patients with active granuloma-forming disease could be induced when they were challenged with increased sunlight exposure or dosed with vitamin D, leading to a subsequent increase in serum  $25(\text{OH})\text{D}$  levels [13,14]. Next was the discovery that the downstream immune action of  $1,25(\text{OH})_2\text{D}$  was mediated through upregulated expression of the VDR in antigen-activated innate and adaptive immune cells in local inflammatory microenvironments, especially in the lung [104]. Last was recognition of the fact that the link between the local production and immune action of calcitriol is largely mediated through the unique ability of human and higher primate monocytes/macrophages and dendritic cells to transactivate antimicrobial genes (e.g., *cathelicidin antimicrobial peptide* [CAMP]) through the  $1,25(\text{OH})_2\text{D}$ -activated VDR ([105]; see Chapters 9 and 94).

After cleavage from its 18 KD precursor form (hCAP18) inside the innate immune cell, the cationic cleavage peptide, LL-37, becomes the bioactive product of the CAMP gene. LL-37 forms an amphipathic  $\alpha$ -helix when it comes in contact with hydrophobic surfaces, such as microbial membranes, disrupting the ordered arrangement and function of the hydrophobic phospholipid components of the membrane [106,107]. Increases in circulating levels of LL-37 have been observed in bacterial [108], mycobacterial [109–112], and viral [113] infections. Importantly, local concentrations of LL-37 have been observed at the site of infection [114,115].  $1,25(\text{OH})_2\text{D}$  regulation of the production and action of LL-37 to kill microbes, either intracellularly or extracellularly after secretion from an innate immune cell, turns out to be a completely fortuitous event in

nature. It is the consequence of the random insertion of a transposable Alu repeat element containing a positive, cis-acting, consensus vitamin D responsive element (VDRE) in the human CAMP promoter [105]. The end result is  $25(\text{OH})\text{D}$ -driven, intracrine production of  $1,25(\text{OH})_2\text{D}$  via upregulated expression of the CYP27B1 in TLR-activated, VDR-expressing innate immune cells with subsequent transactivation of the CAMP gene.

If the above slate of concerted immune response events is true, then the following set of observations should hold clinically. First, local concentrations of  $1,25(\text{OH})_2\text{D}$  at the site of microbial infection and TLR activation of disease-activated macrophages in patients with macrophage proliferative disease should be increased compared to the concentration found in the general circulation. Proof of this reality was the finding of a steep increase in the pleural fluid:serum concentration of free  $1,25(\text{OH})_2\text{D}$  in patients with active pulmonary tuberculosis [103,104]. Second, the amount of locally produced  $1,25(\text{OH})_2\text{D}$  should be dependent on the concentration of substrate  $25(\text{OH})\text{D}$  available to the intracrine-acting CYP27B1. Proof of this dose-response reality was shown to be the case for alveolar macrophages harvested from patients with the active granuloma-forming disease [3,27]. Third, the production of LL-37 should be positively correlated with  $25(\text{OH})\text{D}$ -driven,  $1,25(\text{OH})_2\text{D}$ -VDR-mediated intracrine expression of the CAMP gene and its bioactive antimicrobial product LL-37. Initial proof of this was demonstrated when serum from vitamin D insufficient subjects, before and after restoration of the serum  $25(\text{OH})\text{D}$  level to normal, was used to condition activated, heterologous [29], or homologous [116] primary human monocyte-macrophages to increase LL-37 production. And fourth, an increase in the amount of circulating  $25(\text{OH})\text{D}$  substrate available to the activated CYP27B1 in human disease-activated macrophages should result in improved clinical outcomes in infected patients. There is now mounting evidence, including from large-scale meta-analyses, that is the case, especially in patients with acute respiratory infections (ARI) of viral origin [117–121] including those with COVID-19 [122].

## 4.2 Microbial infection and the serum $25(\text{OH})\text{D}$ status of the host

Again, it stands to reason that if the above set of circumstances is true, then insufficient  $25(\text{OH})\text{D}$  status of the human host, manifest by low circulating levels of the metabolite (usually defined as a total serum  $25(\text{OH})\text{D}$  level  $<20$  ng/mL or  $70$  nmol/L) should be associated with increased susceptibility to microbial

disease. Indeed, insufficient 25(OH)D in serum has been associated with increased rates of influenza [123], viral upper respiratory tract infection [124,125], pneumonia [126], HIV [127,128], and active tuberculosis [129]. The earliest attempt to reduce the incidence and/or severity of microbial infection with vitamin D dates back to the early twentieth century, when sunlight exposure was used to treat patients with tuberculosis [130]. Despite these early findings, the administration of vitamin D and its metabolites in RCTs of patients with infectious and/or inflammatory diseases was not pursued until almost a century later. The results of these more recent trials have been mixed. The strongest evidence of a vitamin D antimicrobial effect arose from effective supplementation studies in the context of influenza [118] and upper respiratory tract infections [120,131]. Since the onset of the COVID-19 pandemic, VDI has been associated with increased SARS-CoV-2 infection risk [132,133], greater COVID-19 severity [134], and delayed COVID-19 recovery [135], prompting supplementation studies that, although variable in power and design, have shown a reduced requirement for intensive care unit (ICU) treatment among patients hospitalized with COVID-19 [136] and accelerated recovery from pulmonary symptoms in nonhospitalized SARS-CoV-2-infected patients [40].

#### 4.3 Use of immediate-release calcifediol (IRC) and extended-release calcifediol (ERC) in acute respiratory infections (ARI) including COVID-19

Results on the use of IRC in the prevention and treatment of COVID-19 are just starting to appear (e.g., [135,137–139]) with a few trials still ongoing. All indicate that treatment with calcifediol slows the onset and/or reduces adverse outcomes in COVID-19 disease. The problem with these studies is that they were not performed in a fully prospective, randomized, double-blind, placebo-controlled manner.

To fill this knowledge gap, we performed a pilot RCT to investigate the effect of raising serum total 25(OH)D levels to the range of 50–100 ng/mL with oral extended-release calcifediol (ERC) on time to symptom resolution in outpatients with mild to moderate COVID-19 [40]. The study focused on outpatients rather than on hospitalized patients because effective early intervention could prevent hospitalizations. The trial was a prospective, multicenter, randomized, double-blind, placebo-controlled study comparing ERC to placebo treatment (1:1) of 160 outpatients with COVID-19 enrolled between November 2020 and October 2021. Subjects were treated for 4 weeks with ERC 30 µg/capsules, 300 µg on Days 1–3 and 60 µg on Days 4–27) or

placebo. Primary endpoints were raising serum 25(OH)D to  $\geq 50$  ng/mL and resolution time for aggregated self-reported symptoms. Secondary endpoints included symptom resolution time versus the serum 25(OH)D level. A total of 171 subjects were randomized, 160 were treated, and 134 (65 ERC and 69 placebo) retained to the completion of the trial (per-protocol population). Average age (43 years), gender (59% female), racial makeup (80% Hispanic, 12% White, 7% African American, 1% Other), BMI (76% overweight and 40% obese), and comorbidities (26%) that increase susceptibility to clinical COVID-19 were not significantly different between the ERC and placebo groups.

The mean ( $\pm$ SE) baseline serum 25(OH)D was in the “normal” range for bone health ( $\geq 30$  ng/mL) in both the ERC-treated and placebo groups ( $37 \pm 1$  ng/mL) (Fig. 73.3, Panel A). This regimen of ERC increased the mean total serum 25(OH)D to  $82 \pm 4$  ng/mL by Day 7 of treatment ( $P < .0001$ ) and caused 86% of ERC-treated subjects to attain a 25(OH)D level  $\geq 50$  ng/mL. The corresponding level in the placebo-treated group was significantly lower at all evaluation time points and unchanged over the course of the trial (Fig. 73.3, Panel A). Regardless of the starting serum 25(OH)D level, ERC-treated subjects had significant increases in their 25(OH)D ( $P < .005$ ) by the end of the 4-week treatment period with no significant correlation between the magnitude of the ERC-induced increase in serum 25(OH)D based on the subject’s starting 25(OH)D level (Fig. 73.3, Panel B). Resolution time for five aggregated COVID-19 symptoms was unchanged by ERC, because two composite nonrespiratory symptoms (body aches/pains, chills/shivering) were unchanged by either ERC or placebo treatment. Prespecified analyses showed that the triad pulmonary symptoms, trouble breathing, chest congestion, and dry or hacking cough, tended to resolve earlier when serum 25(OH)D levels reached  $\geq 50$  ng/mL, but statistical significance was limited by small sample size and noncompliance; serum 25(OH)D increased in seven placebo subjects (unauthorized supplementation) but not in five ERC subjects (failure to dose).

A post hoc analysis of results from subjects in the per-protocol population demonstrated that respiratory symptoms resolved 3.0 days faster when 25(OH)D was elevated at Days 7 and 14 ( $P < .05$ ; Fig. 73.3, Panel A). Chest congestion, in particular, resolved 4.0 days faster with net 25(OH)D increases of  $\geq 25$  ng/mL ( $P < .05$ ). All of these significant changes in symptom resolution occurred in the first 2 weeks of ERC treatment. Serum 25(OH)D levels of  $\geq 50$  ng/mL have been suggested to support intracellular generation of 1,25(OH)<sub>2</sub>D, activation of the VDR, transactivation of the CAMP gene, and production and release of LL37 to combat SARS-CoV-2 proliferation in the host [107]. Compared to no

**FIGURE 73.3** **Panel A** shows the mean ( $\pm$ SE) total serum 25-hydroxyvitamin D (25(OH)D) by study day and per-protocol treatment group (closed bars: extended-release calcifediol [ERC]; open bars: placebo). Percentages at the base of each bar indicate the proportion of subjects achieving serum 25(OH)D levels of at least 50 ng/mL. Asterisks indicate significant differences between treatment groups ( $P < .0001$ ). **Panel B** depicts the mean ( $\pm$ SE) increases in serum total 25(OH)D during ERC treatment by baseline serum 25(OH)D in the per-protocol population. The horizontal dotted line indicates the mean increase for all treated subjects. All increases were significant ( $P < .005$ ). **Panel C** displays Kaplan–Meier curves of the time to resolution of a composite of three pulmonary symptoms (trouble breathing, chest congestion, dry or hacking cough) in subjects in the per-protocol population achieving increases versus no increases in the serum total 25(OH)D level. The difference between the plotted curves is significant ( $P < .05$ ). Reprinted with permission from Ref. [40].

change in placebo-treated subjects, ERC-treated subjects showed a significant increase in serum calcitriol ( $P < .005$ ) and a 10% increase in the serum LL37 level at the conclusion of the 4-week trial. It is possible that these elevations in the circulation reflect their elevated concentrations in the extravascular inflammatory micro-environment of the lung.

This study's inability to show more significant differences in time to resolution for respiratory symptoms is likely due to (i) the small sample size of the pilot, (ii) the fact that 17% of subjects assigned to placebo treatment unexpectedly had serum 25(OH)D levels  $\geq 50$  ng/mL at baseline, (iii) dosing noncompliance, and (iv) delays between onset of symptoms and diagnosis of COVID-19 and between diagnosis and initiation of treatment. The observed positive effect of elevation of the serum 25(OH)D on the resolution of respiratory symptoms is based on a post hoc analysis and needs confirmation in a larger study. Despite these issues, the study recorded some interesting results. For example, aggressive and persistent elevation of the serum 25(OH)D into the 50–100 ng/mL range for 4 weeks with ERC was without calcemic side effects of any sort. This indicates that it is safe to gradually drive serum 25(OH)D levels with ERC to the range where the local extra-renal production of 1,25(OH)<sub>2</sub>D occurs (see Chapter 11) for weeks at a time when antimicrobial activity is most needed for ARI, including COVID-19. Also interesting is the fact that pulmonary symptom resolution was not predicated on the subject being vitamin D insufficient at the beginning of the study, suggesting that it was secondary to the robust incremental increase in the serum 25(OH)D level achieved with ERC treatment.

This study with ERC differed from previous evaluations of vitamin D supplementation in COVID-19, primarily because it was designed to target a high serum 25(OH)D exposure (50–100 ng/mL) with downward dose adjustment, as needed. The known adverse impact of adipose tissue on 25(OH)D bioavailability with vitamin D supplements is readily overcome with ERC [85]. Prescription and nonprescription supplements of cholecalciferol and ergocalciferol are fat-soluble, poorly absorbed in the intestine, accumulate preferentially in adipose tissue [140], possess low affinities for serum DBP [141] and are poorly mobilized from adipose into circulation for hepatic activation [47,48]. Such supplements have multi-day delays in raising the serum 25(OH)D level and prove to be unreliable in raising 25(OH)D in overweight or obese patients who are at high risk for COVID-19 [77,95]. By contrast, calcifediol requires no hepatic activation, is more water soluble, and avidly binds to DBP, reducing accumulation in adipose tissue and enabling ready availability to peripheral tissues, including virus-activated immune cells containing CYP27B1. Collectively, this also means that

calcifediol dosing can be stopped abruptly with an expected decrease in the serum calcifediol level soon to follow; this sort of dose adjustment:rapid response relationship is not possible with treatment with cholecalciferol and ergocalciferol, especially when the adipose reservoir of the host is great.

Consistent with the excellent safety profile established for ERC in CKD patients [21], in this study, the slow-release formulation of ERC safely achieved high serum 25(OH)D exposure (50–100 ng/mL). Persistently elevated serum levels of 25(OH)D in this range have been of concern for vitamin D supplement administration [35]. Compounding this concern is the reported inverse relationship between the baseline 25(OH)D levels and observed increases seen with vitamin D supplementation regimens [142]. However, as previously stated, this relationship was not observed in this ERC trial, perhaps owing to the fact that the baseline serum 25(OH)D in both the ERC and placebo control groups were  $>30$  ng/mL. Safety endpoints and serum biomarkers of the calcemic actions of ERC treatment showed no clinically meaningful changes. Serum calcium and phosphorus, circulating PTH, and estimated glomerular filtration rate (eGFR) all remained stable. Episodes of hypercalcemia or hyperphosphatemia were not observed, even in subjects whose serum 25(OH)D exceeded 100 ng/mL during the course of the trial. This is perhaps not surprising as this was a short-term study aimed at altering the course of ARI with SARS-CoV2 infection.

The current ERC trial also varies from trials using IRC to boost the serum 25(OH)D level in COVID-19 subjects. The primary difference resides in the design of the pilot ERC study. Unlike all other reports [135,137–139], it was a prospective, randomized, double-blind, placebo-controlled trial that used an extended-release, not an immediate-release, formulation of calcifediol, avoiding the uncertain dose-response effect with IRC. Oral IRC results in a more rapid release of calcifediol in the proximal bowel for absorption and a lower achieved 25(OH)D level in the serum [139]. On the other hand, the release of calcifediol from ERC is gradual, continues over a period of 12 h (based on in vitro dissolution), and likely occurs primarily in the colon [21]. The conclusion from this randomized, double-blind, placebo-controlled pilot study was that daily oral administration of ERC (60  $\mu$ g), after a 3-day oral loading dose of 300  $\mu$ g, for 4 weeks was effective in rapidly, robustly, and safely increasing serum 25(OH)D in COVID-19 outpatients to levels supporting the immune cell synthesis and secretion of 1,25(OH)<sub>2</sub>D into the inflammatory microenvironment of the SARS-CoV2 infected lung (see Table 73.1) with the possibility to accelerate the resolution of respiratory symptoms and mitigation of pneumonia risk.

## 5. Conclusion

This chapter attempts to outline three dominant clinical situations in which the use of calcifediol may be superior to supplementation with ergocalciferol or cholecalciferol. These are: (1) endocrine-mediated SHPT associated with VDI (serum 25(OH)D < 20 ng/mL or 30 ng/mL) and bone loss; (2) more severe SHPT associated with CKD, relative VDI, and endocrine-mediated bone loss; and (3) microbial infections, particularly viral disease in the lung (e.g., influenza and COVID-19) where relatively high levels of 25(OH)D (50–100 ng/mL range) are required to satisfy the substrate needs of the CYP27B1 expressed in activated innate immune cells (e.g., macrophages) in order to drive 1,25(OH)<sub>2</sub>D-VDR-anti-microbial response in the local, tissue-based inflammatory microenvironment.

## 6. Summary points

- The key advantages of raising serum 25(OH)D with oral calcifediol using either immediate-release (IRC) or extended-release (ERC) preparations vs. oral vitamin D supplements can be summarized as follows: calcifediol (i) is bound with high affinity by the serum DBP which reduces the total body volume of distribution of this metabolite to adipose tissue, (ii) bypasses the need for hepatic 25-hydroxylation, and (iii) can raise serum 25(OH)D more effectively.
- Among orally administered vitamin D repletion therapies, ERC appears to be safer and more effective than IRC in raising serum 25(OH)D to higher targets (e.g., ≥50 ng/mL), and both calcifediol formulations (ERC and IRC) are far more effective than vitamin D supplements (ergocalciferol or cholecalciferol). More comparative data from RCTs are needed for confirmation.
- Aggressive, short-term, oral supplementation with calcifediol can significantly increase serum 25(OH)D and potentially improve outcomes in subjects with acute, viral upper respiratory tract infection (e.g., influenza).
- In a pilot RCT, a blinded comparison of symptomatic, placebo-treated COVID-19 outpatients to those treated with ERC showed that ERC safely and effectively increased mean serum 25(OH)D levels to approximately 80 ng/mL and accelerated the mean resolution time for pulmonary symptoms by 3 days in the immediate 2-week treatment interval. This provided preliminary evidence for the safety and efficacy of ERC in the treatment of symptomatic COVID-19 especially early in the course of the disease.
- Increasing the serum 25(OH)D in symptomatic COVID-19 outpatients to 50–100 ng/mL, the “tissue immunoactive range,” with ERC appears to reduce pulmonary symptoms even in those patients who have a mean baseline 25(OH)D level in the normal range (≥30 ng/mL). This suggests that the immunoactions of calcifediol are related to the elevation of 25(OH)D to 50–100 ng/mL and are not confined to only those with VDI.

# Vitamin D and organ transplantation

*Joseph Raphael<sup>1</sup>, Emily M. Stein<sup>1</sup> and Elizabeth Shane<sup>2</sup>*

<sup>1</sup>Hospital for Special Surgery, New York, NY, United States <sup>2</sup>Vagelos College of Physicians and Surgeons, New York, NY, United States

## OBJECTIVES

- Review the role of vitamin D in immune function, specifically as it relates to the transplant population.
- Describe the risk factors for vitamin D deficiency in patients with end stage pulmonary disease, liver failure, congestive heart failure, and chronic kidney disease prior to organ transplantation.
- Examine the prevalence of vitamin D deficiency at the time of, shortly after, and in long-term organ transplant recipients.
- Summarize interventional trials evaluating 1,25(OH)<sub>2</sub>D and its analogs for the prevention and treatment of bone loss following solid organ transplantation.

## 1. Introduction

There are many skeletal and extraskeletal sequelae of vitamin D deficiency among organ transplant patients. Vitamin D deficiency can result in secondary hyperparathyroidism, bone loss, and fracture, as well as muscle weakness and falls [1–3]. Insulin resistance (see [Chapters 75 and 76](#)), hypertension ([Chapter 41](#)), and malignancy ([Chapters 84–92](#)) are important extraskeletal sequelae [4–7]. The role of vitamin D in regulating immune function is of potential importance among transplant patients [8] (see [Chapters 94–106](#)). In this chapter, we will review the role of vitamin D in immune function as it relates to the transplant population. The prevalence of vitamin D deficiency in organ transplant

candidates and in long-term transplant recipients will be examined, with assessment of vitamin D status based on 25(OH)D measurements, currently the best available indicator of vitamin D stores. Finally, we will summarize interventional trials evaluating 1,25(OH)<sub>2</sub>D and its analogs for the prevention and treatment of bone loss following solid organ transplantation.

## 2. Effects of vitamin D on immunity and graft rejection

### 2.1 Role of vitamin D in allograft rejection

The role of vitamin D in the regulation of immune cell proliferation, differentiation, and responsiveness has been summarized in several reviews [9–14] and other chapters in this book ([Chapters 94–106](#)). In animal studies, administration of 1,25(OH)<sub>2</sub>D (calcitriol) prevented acute allograft rejection following kidney [15], heart [16], and liver [17,18] transplantation. In a recent animal study, administration of nebulized 1,25(OH)<sub>2</sub>D reduced inflammatory cells in the bronchoalveolar lavage [19]. Data from human studies have yielded mixed results. Pretransplant vitamin D insufficiency in pediatric liver transplant candidates was directly associated with T cell–mediated rejection during the first year posttransplant [20]. In retrospective studies of kidney transplant recipients, calcitriol supplementation was associated with fewer episodes of acute cellular rejection [21], reduced glucocorticoid requirements [22], and decreased expression of costimulatory and human leukocyte antigen–antigen D related (HLA-DR) molecules [23], suggesting a possible mechanism for improved allograft survival. Briffa et al. found that patients treated with 1,25(OH)<sub>2</sub>D (calcitriol) following

heart transplantation had a reduction in their requirement for cyclosporine, a calcineurin inhibitor that is a commonly used immunosuppressive medication [24]. However, in our clinical trial of heart transplant recipients treated with calcitriol, we did not observe lower cyclosporine or prednisone doses in patients randomized to calcitriol [25]. A recent prospective cohort study of adult kidney transplant recipients did not find an association between serum 25(OH)D or 1,25(OH)<sub>2</sub>D and risk of rejection following transplantation [26]. In a prospective-controlled study of liver transplant patients, calcitriol use was associated with both lower rates of acute rejection and an increase in regulatory T cells as assessed by flow cytometry, suggesting that calcitriol may mitigate acute rejection through enhancing T cell function [27]. Further prospective human studies are needed to explore the role of 1,25(OH)<sub>2</sub>D and parent vitamin D in prevention of graft rejection and infection after transplantation.

## 2.2 Immune effects of vitamin D

Interest in the role of vitamin D in immunity has burgeoned since the COVID-19 pandemic and has led to a surge in the number of publications on this topic, well beyond the scope of this chapter [28–31] (see Chapter 99). Monocytes and macrophages express the enzyme 1 $\alpha$ -hydroxylase (CYP27B1) and produce 1,25(OH)<sub>2</sub>D, which has intracellular antimicrobial effects and can also interact with and govern the cytokine profiles of activated T and B lymphocytes in the local environment (see Chapter 9) [32]. The ability of monocytes and macrophages to synthesize sufficient 1,25(OH)<sub>2</sub>D is dependent on availability of adequate serum concentrations of 25(OH)D and therefore increases in response to vitamin D supplementation [33]. When there is insufficient 25(OH)D available, immunity may be impaired because local production of 1,25(OH)<sub>2</sub>D will decline. Subsequent decreased binding of 1,25(OH)<sub>2</sub>D to the macrophage vitamin D receptor (VDR) will result in reduced antimicrobial activity against ingested microbes [32] (see Chapters 94 and 95). The antimicrobial actions of 1,25(OH)<sub>2</sub>D also occur in barrier epithelial cells of the skin [34,35], gut [36], colon [37], and lung [38–40], sites which may be of particular importance in transplant recipients. Vitamin D may also play an important role in mitigating oxidative stress in the liver and preserving hepatic function [41] (see Chapter 77). Vitamin D has been shown to protect against bacterial and viral infections as well as tuberculosis in many prior laboratory-based and observational clinical investigations [34], [42–49] (see Chapters 94 and 95). In nude mice, 1 $\alpha$ -hydroxyvitamin D (1 $\alpha$ -OHD, metabolized to 1,25(OH)<sub>2</sub>D by 25-hydroxylase)

inhibited rejection mediated by alloreactive CD4(+) memory T cells and prolonged cardiac allograft survival [50]. Research using genome-wide analyses suggests that both VDR and 1 $\alpha$ -hydroxylase expressions are increased in macrophages following a pathogen challenge [51,52]. Vitamin D may act through cytokine signaling via the extrarenal 1 $\alpha$ -hydroxylase to influence intracrine vitamin D pathways, which can enhance or abrogate the systemic response to 25(OH)D [51,53]. Vitamin D may also exert its effects at the epigenetic level by modulating microRNA function, which can affect the transcriptional regulation of gene expression [54,55] (see Chapters 12 and 14).

In a population-based study, upper respiratory tract infections were more common in individuals with lower 25(OH)D levels [56]. However, a recent randomized controlled trial conducted in children in Mongolia found that weekly supplementation of 14,000 IU of vitamin D<sub>3</sub> over 3 years did not lower risk of tuberculosis infection, tuberculosis disease, or other acute respiratory infection compared with placebo [57]. Among renal transplant recipients, those with vitamin D deficiency were found to have an increased risk of urinary tract, bacterial, or viral infections after renal transplantation [58–61].

## 3. Vitamin D deficiency prior to organ transplant

Vitamin D insufficiency and deficiency have been described in patients with end-stage pulmonary disease [62,63], liver failure [20], [64–68], congestive heart failure [69,70], and chronic kidney disease (CKD) [71–73]. Several factors place these patients at particular risk for vitamin D deficiency, including limited sunlight exposure and low dietary intake of vitamin D-containing foods. Furthermore, hepatic dysfunction, which can result from intrinsic liver disease or from hepatic congestion in heart failure patients, may contribute (Table 74.1). In this chapter, we will define insufficiency as 25(OH)D < 30 ng/mL, deficiency as 25(OH)D < 20 ng/mL, and severe deficiency as 25(OH)D < 10 ng/mL [74].

### 3.1 Vitamin D deficiency in patients with end-stage pulmonary disease

Patients with end-stage pulmonary disease commonly have 25(OH)D deficiency. Severe vitamin D deficiency has been reported in 20%–50% of these individuals [62,75,76]. In patients with advanced pulmonary disease, low 25(OH)D was associated with lower fat mass, obstructive pulmonary disease, and low dietary vitamin D intake and was a predictor of decreased walking distance and decreased forced expiratory

**TABLE 74.1** Risk factors for vitamin D deficiency in organ transplant patients.

- African American race
- Limited sunlight exposure, northern latitude, and winter months
- Low dietary intake of vitamin D
- Low fat mass
- Low serum albumin
- Hepatic dysfunction
- Obstructive pulmonary disease
- Renal insufficiency
- Diabetes
- Malabsorption
- Poor general health
- Female sex<sup>a</sup>
- Glucocorticoid use<sup>a</sup>—increases catabolism of 25(OH)D
- Organ transplanted<sup>a</sup>—liver-transplanted recipients may be at increased risk
- Recent transplantation<sup>a</sup>
- Proteinuria<sup>a</sup>
- Use of angiotensin-converting enzyme inhibitors or aldosterone receptor blockers<sup>a</sup>

<sup>a</sup>Risk factor specifically demonstrated following transplantation.

volume in 1 s ( $FEV_1$ ) [77,78]. In patients with cystic fibrosis (CF), a common indication for lung transplantation, we have observed that vitamin D deficiency is extremely common, related in part to pancreatic insufficiency. Despite supplementation, bone mineral density (BMD) was significantly lower in the D-deficient patients with CF [79]. Vitamin D deficiency is associated with osteoporosis and fractures in other cohorts with CF [79–81]. A recent study indicates that adults with CF and vitamin D deficiency are at higher risk of developing CF-related diabetes and are at risk for earlier onset of CF-related diabetes [82].

### 3.2 Vitamin D deficiency in patients with liver failure

Vitamin D deficiency is also very common in patients with severe liver disease, affecting over 80% of liver transplant candidates [66,83,84]. In one study of patients awaiting transplantation, mean 25(OH)D was 9 ng/mL, in the severely deficient range [64]. In a study of 107 liver transplant candidates, 84% were vitamin D deficient at

the time of liver transplant evaluation and 74% remained deficient at transplant [66]. In another cohort, cirrhotic patients referred for liver transplantation had lower serum 25(OH)D, 1,25(OH)<sub>2</sub>D, intact parathyroid hormone (PTH), and osteocalcin and higher urinary hydroxyproline excretion compared with controls [85]. PTH may have been low in the setting of vitamin D deficiency due to low intracellular magnesium, which can lead to reduced PTH release; however, this was not directly measured by the investigators. Also, it cannot be assumed that these patients had increased bone turnover based upon the elevated urinary hydroxyproline, because this marker can also be elevated in cirrhosis due to increased collagenolysis [85]. Another study found that a model for end-stage liver disease (MELD) score of greater than 15, indicative of worse disease and poorer health, was associated with lower serum 25(OH)D [86]. It is conceivable that free vitamin D may not be as low as suggested by total serum 25(OH)D measurements in patients with severe liver disease, who may have lower levels of vitamin D-binding protein (DBP) as a result of reduced hepatic synthetic capacity.

### 3.3 Vitamin D deficiency in patients with congestive heart failure

Vitamin D deficiency is common among patients with heart failure [87]. We reported that the majority of patients with congestive heart failure had vitamin D deficiency (mean 25(OH)D 18 ng/mL) and that 18% of patients had severe deficiency (<9 ng/mL). Patients with lower 25(OH)D had lower serum calcium, phosphorus, and albumin, and higher total alkaline phosphatase activity, and bone resorption markers. No association between 25(OH)D and 1,25(OH)<sub>2</sub>D was found. Serum PTH was significantly lower in those patients in the highest tertile of 25(OH)D [69]. In an observational study of patients with end-stage heart failure, lower circulating calcitriol levels were associated with poor clinical outcomes and death [88]. Vitamin D deficiency has been associated with left ventricular hypertrophy, vascular dysfunction, and activation of the renin-angiotensin system [89]. However, while vitamin D deficiency is associated with increased mortality and morbidity in patients in the aforementioned observational study, a recent randomized controlled trial found no significant improvement in blood pressure or 6-min walk test after administration of 50,000 IU of vitamin D<sub>3</sub>/week for 8 weeks [90]. Further, in a 3-year randomized clinical trial, supplementation of 4000 IU of vitamin D<sub>3</sub> daily did not reduce mortality in patients with advanced heart failure [91].

### 3.4 Vitamin D deficiency in patients with chronic kidney disease

In patients with CKD, glomerular loss leads to declining renal function and subsequent  $1,25(\text{OH})_2\text{D}$  deficiency [92,93]. Patients with CKD also frequently have  $25(\text{OH})\text{D}$  deficiency [71,72], [93–95]; lower  $25(\text{OH})\text{D}$  in this population is associated with worse kidney function, immune dysfunction, and possibly increased risk of infection [96–98]. A recent study indicates vitamin D may serve as a biomarker of tubular health and may be a predictor of worsening kidney function in stage 3 and 4 kidney disease patients [99]. In a population-based study, 71% of patients with stage 3 and 83% of those with stage 4 CKD had  $25(\text{OH})\text{D}$  insufficiency and 14% of patients with stage 3 and 26% with stage 4 CKD had severe deficiency [72]. In another study, 39% of CKD patients had  $25(\text{OH})\text{D}$  between 16 and 30 ng/mL, 33% less than 16 ng/mL, and 6% less than 5 ng/mL [71]. Factors associated with low  $25(\text{OH})\text{D}$  in CKD patients include female sex, African American race, latitude, season, diabetes, and low serum albumin [93,100]. Baseline  $25(\text{OH})\text{D}$  was an independent predictor of death over 6 years in patients with CKD [96]; this finding most likely reflects the poorer general health of the subjects with vitamin D deficiency at baseline.

## 4. Vitamin D deficiency following organ transplant

Vitamin D insufficiency has been reported in 51%–97% of organ transplant recipients and severe deficiency in 26%–33% [101–106]. Variability in these estimates relates to the type of organ transplanted, patient population, and assay utilized for measurement of  $25(\text{OH})\text{D}$  [107–110]. Poor health following transplant can lead to decreased dietary intake of vitamin D-containing foods. In addition, many organ transplant recipients dramatically limit sun exposure because they are at increased risk for skin cancer [111,112]. Furthermore, animal studies suggest that glucocorticoids, commonly used for posttransplant immunosuppression, may increase catabolism of  $25(\text{OH})\text{D}$  [113,114]. Patient factors that have been shown to be associated with vitamin D deficiency after transplantation include African American race [105,115], avoidance of sun, low dietary intake [104], and transplantation during winter months [115,116]. Variations in  $25(\text{OH})\text{D}$  related to sun exposure have not been observed in all studies [101], perhaps because sun exposure is so limited in the most severely ill patients.

### 4.1 Vitamin D deficiency at the time of organ transplantation

Few studies have examined vitamin D levels at the time of transplantation. One study found that 80% of recently transplanted lung transplant recipients were  $25(\text{OH})\text{D}$  deficient [117] and that low  $25(\text{OH})\text{D}$  levels measured during the 100 days immediately before or after lung transplant were associated with increased incidence of both acute rejection and infection in both the immediate posttransplant period and up to 1 year later [117]. In pediatric liver transplant patients, vitamin D insufficiency prior to transplant was associated with posttransplant development of T cell–mediated rejection [20]. In heart and liver transplant recipients evaluated immediately after transplantation, we found that 91% of patients had serum vitamin D insufficiency ( $25(\text{OH})\text{D}$  levels <30 ng/mL), 55% had deficiency ( $25(\text{OH})\text{D}$  <20 ng/mL), and 16% had severe deficiency ( $25(\text{OH})\text{D}$  levels <10 ng/mL). Vitamin D levels were significantly lower in liver compared with heart transplant recipients (Fig. 74.1), likely related to malabsorption and impaired hepatic  $25$ -hydroxylation of vitamin D in liver transplant patients. Lower levels of vitamin D-binding protein (DBP) may also contribute to lower  $25(\text{OH})\text{D}$  in liver transplant recipients, although we did not measure DBP in that study [101]. Vitamin D insufficiency was found in 59% of patients at the time of renal transplantation, with severe deficiency in 29% [115].

### 4.2 Vitamin D deficiency in long-term transplant recipients

In kidney transplant patients, vitamin D deficiency is common and severe several years after transplantation [102,105], [118–120]. In one cohort, 97% of renal transplant recipients had insufficient  $25(\text{OH})\text{D}$  levels. Although not directly associated with vertebral fractures, low  $25(\text{OH})\text{D}$  was associated with higher PTH, which was significantly associated with vertebral fractures [121]. In another study of renal transplant recipients who were on average 7 years posttransplant, serum  $25(\text{OH})\text{D}$  levels were lower than in age-matched controls, mean serum  $25(\text{OH})\text{D}$  was 10 ng/mL, and one-third of patients had undetectable levels [102]. In a study of 293 kidney transplant recipients, low  $25(\text{OH})\text{D}$  levels predicted both decline in glomerular filtration rate and requirement for glucocorticoids to treat allograft rejection within the first 10 years after kidney transplantation [122]. In 435 renal transplant patients, who were followed for up to 7.5 years from transplant, there was an inverse association of  $25(\text{OH})\text{D}$  levels with mortality, even after adjustment for potential cofounders such as

**FIGURE 74.1** Comparison of serum 25-hydroxyvitamin D levels at the time of organ transplantation in heart and liver transplant recipients. Adapted from Ref. [101].

renal function (HR 0.68, 95% CI 0.52–0.89) [123]. Additionally, renal transplant patients with endothelial dysfunction, a marker of cardiovascular health and mortality, had significantly lower vitamin D levels than those with normal endothelial function [124]. In more recent studies, vitamin D deficiency is still common, but the prevalence is lower, possibly because of greater awareness and treatment of vitamin D deficiency [125].

Factors associated with low 25(OH)D in renal transplant recipients include African American race [105], female sex, measurement in autumn and winter months [105], recency of transplantation [118], inadequate dietary vitamin D intake (reported in 87%–91% of patients [126]), proteinuria [127], and use of angiotensin-converting enzyme inhibitors or aldosterone receptor blockers [118]. Persistent elevations in fibroblast growth factor 23 (FGF23) after kidney transplantation may result in lower serum 1,25(OH)<sub>2</sub>D levels through multiple pathways. High FGF23 levels after renal transplant may contribute to PTH resistance [128,129].

The optimal amount of vitamin D that is both beneficial and safe in transplant recipients remains to be determined, as does the target serum 25(OH)D level [130]. Data to address this knowledge gap may be available in the future through the vitamin D supplementation in renal transplant recipients trial, which is a prospective, multicenter, randomized trial of the efficacy and safety of cholecalciferol 100,000 IU monthly to maintain serum levels of 25(OH)D between 30 and 80 ng/mL [131].

Serum 25(OH)D concentrations are low in liver transplant recipients, likely because of disease-related factors such as malabsorption, impaired hepatic 25-hydroxylation of vitamin D, and reduced production of DBP [101,132]. In long-term liver transplant

recipients, 65%–68% had 25(OH)D levels below 15 ng/mL [103,133]. Patients with lower 25(OH)D levels also had lower Z-scores at the FN [133]. Many authors report increases in both 25(OH)D and PTH following liver transplantation [64,65,134,135]. However, others have not found significant changes [136–138]. Reported increases appear to be sustained for at least 3–4 years following transplantation [64,134]. In a recent observational study, lower baseline, preoperative 25(OH)D was associated with greater severity of liver disease. Moreover, lower serum 25(OH)D on postoperative day 28 was associated with incomplete graft recovery [132]. In an observational study of liver transplant patients, those supplemented with cholecalciferol had fewer rejection episodes [86].

In contrast, in a randomized placebo controlled trial, once monthly oral vitamin D supplementation of 100,000 IU after lung transplantation was not associated with chronic lung allograft dysfunction, lymphocytic bronchiolitis, respiratory infections, or pulmonary and systemic inflammation [139]. Whether smaller, but more frequent doses would have a different effect is an important question for future studies.

In cardiac transplant patients, vitamin D deficiency is frequently reported [69,140,141]. Furthermore, low concentrations of 1,25(OH)<sub>2</sub>D measured 21 days posttransplantation were directly associated with 1-year mortality (Fig. 74.2) [142]. After cardiac transplantation, sustained increases in serum creatinine [143–145] and decreases in 1,25(OH)<sub>2</sub>D are observed [142,144,145]. Whether this observation reflects the possibility that low calcitriol is a marker of renal dysfunction or poorer health or alternatively reflects a causal relationship

**FIGURE 74.2** Kaplan–Meier survival estimates in cardiac transplant recipients according to categories of serum calcitriol concentrations 21 days after transplant (log-rank test  $P < .001$ ). Adapted from Ref. [142].

between calcitriol and mortality requires further investigation. Factors associated with vitamin D deficiency in transplant recipients are detailed in [Table 74.1](#).

### 5. Treatment of posttransplant bone loss with vitamin D and analogs

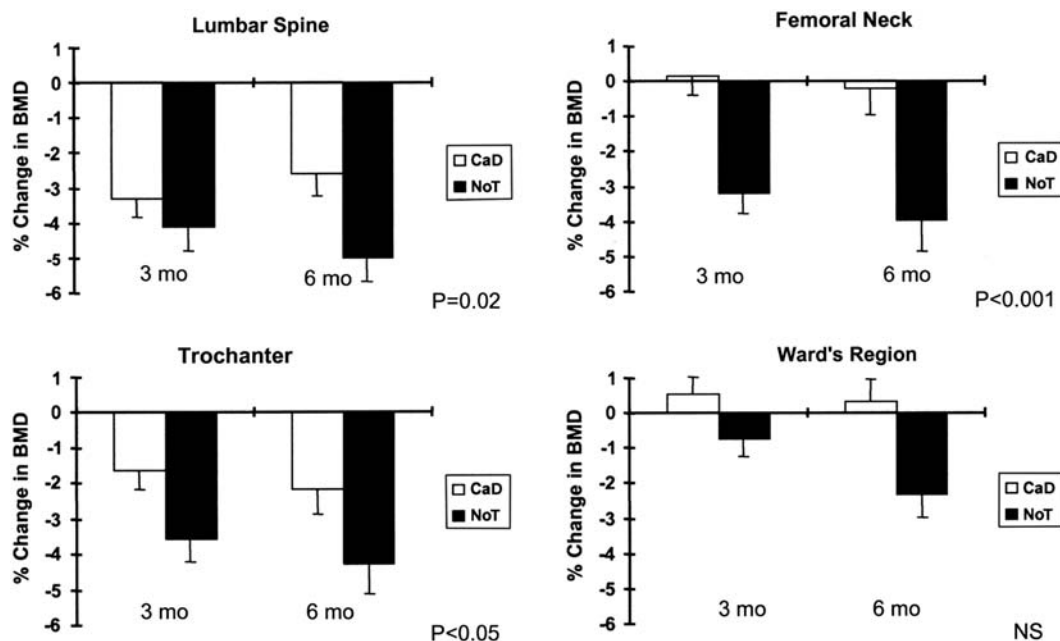

Vitamin D and its analogs have been used to prevent or treat osteoporosis after transplantation [146]. These agents may influence posttransplantation bone loss through several mechanisms. They may overcome glucocorticoid-induced decreases in intestinal calcium absorption, reduce secondary hyperparathyroidism, promote differentiation of osteoblast precursors into mature cells, or influence the immune system and potentiate the immunosuppressive action of calcineurin inhibitors and prednisone, thus reducing the required dose of these drugs [24,98,147,148].

The majority of older observational studies that documented high rates of bone loss after organ transplantation included at least 400–800 IU of parent vitamin D in the posttransplant regimen; thus, it is clear that the recommended daily allowance for vitamin D is not sufficient to prevent posttransplantation bone loss. In two studies, parent vitamin D, at doses of 800 IU daily [149] or 25,000 IU monthly [150], did not prevent bone loss after kidney transplantation. In a recent observational study, it was reported that supplementation with 25(OH)D in doses of 25,000 IU/week for 12 weeks followed by 1500 IU/day for 2 years was not associated with changes in BMD over 2 years in kidney transplant

recipients [151]. However, in view of data summarized earlier in the chapter suggesting that adequacy of vitamin D or therapy with vitamin D is associated with better immune function, a number of organizations including the International Society for Heart and Lung Transplantation, American Association for the Study of Liver Disease, and the Kidney Disease Improving Global Outcomes recommend 400–1000 IU of vitamin D daily for recipients of solid organ transplants [152–155]. In a recent randomized control trial, 4000 IU of daily vitamin D (cholecalciferol) attenuated spine bone loss in renal transplant recipients [156].

More active forms of vitamin D may have greater efficacy than simple vitamin D. Calcidiol (25(OH)D) prevented bone loss and increased LS BMD after cardiac transplantation [157]. When administered immediately after kidney transplantation, alfacalcidol (1 $\alpha$ -OHD) prevented or attenuated bone loss at the LS and FN [158–161]. De Sevaux and colleagues [160] found that alfacalcidol treatment during the first 6 months following renal transplant attenuated bone loss at the LS and greater trochanter and prevented loss at the FN ([Fig. 74.3](#)). Several studies have found increased BMD at the lumbar spine (LS) and femoral neck (FN) in renal transplant patients receiving activated vitamin D (calcitriol and alfacalcidol) [131,158]. Barros et al. found that calcifediol (calcidiol) administered either monthly or biweekly at a 266 mcg/dose safely and effectively lowered PTH and raised 25(OH)D levels in 168 renal transplant patients with a functioning allograft for more than 6 months [162].

In kidney transplant patients, even though there is an increase in calcitriol production by the transplanted

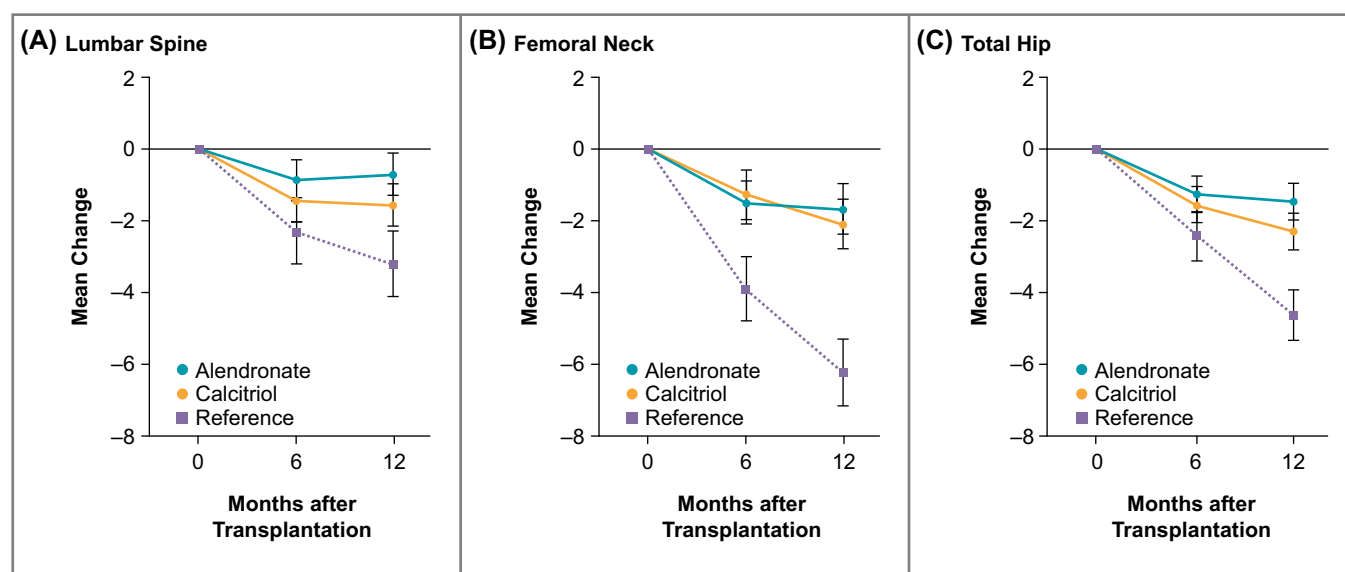

**FIGURE 74.3** Change in bone mineral density in renal transplant recipients treated with calcitriol or placebo (% from baseline  $\pm$  SE; significance shown for differences between groups at 6 months). Adapted from Ref. [160].

kidney, it may be inadequate to suppress excess PTH secretion by hyperplastic parathyroid glands [163]. Calcitriol treatment may be of particular benefit in these patients [22]. Treatment with calcitriol may prevent hyperparathyroidism after cardiac transplant as well [25]. Some studies have found beneficial effects on BMD at doses greater than 0.5  $\mu\text{g}$  per day, although this finding is not uniform. Calcitriol given during the first year after kidney transplantation was associated with an increase in lumbar spine (LS), femoral neck (FN), and forearm BMD [164]. In another study of renal transplant recipients, intermittent calcitriol and calcium prevented bone loss at the total hip but not LS [165]. In a stratified, placebo-controlled randomized study, in which heart and lung transplant recipients received calcitriol or placebo for 12 or 24 months after transplantation [166], LS bone loss was minimal and did not differ between groups. At the FN, bone loss at 24 months was significantly reduced but only in the group that received calcitriol for the entire period. In contrast to these results, which suggest that the protective effects of calcitriol are not sustained after cessation of treatment, we found no bone loss at either the spine or hip in cardiac transplant patients when calcitriol was discontinued after the first posttransplant year [167]. In contrast to the aforementioned findings, other studies have failed to find any benefit of calcitriol on BMD after transplant [168–170].

Vitamin D analogs have been compared with bisphosphonates in several studies, with mixed results. In a randomized trial, we found that the bisphosphonate alendronate (10 mg daily) or calcitriol (0.25  $\mu\text{g}$  twice daily) given immediately after cardiac transplant provided similar protection against bone loss at the spine

and hip 1 year after transplant (Fig. 74.4) and that both were superior compared with a reference group receiving only calcium and vitamin D [25]. During the second year after cardiac transplant, BMD remained stable after discontinuation of both drugs [167]. During the first 6 months after heart or lung transplantation, calcitriol prevented bone loss at the spine and hip and was as effective as cyclic etidronate [171]. In liver transplant patients, administration of ibandronate in addition to calcitriol 0.25–1.0  $\mu\text{g}$  daily, calcium 1000 mg daily, and cholecalciferol 800 IU daily led to increases in FN BMD that were maintained throughout the 3-year study period; in contrast, the control group who received calcitriol, calcium, and vitamin D alone experienced decreases in FN BMD [172]. Kidney transplant patients treated with alendronate, calcitriol, and calcium had increases in LS BMD compared with decreases in those who received only calcium and calcitriol [173]. In another trial of long-term kidney-transplanted patients, approximately 5 years after transplantation who were started on either alendronate, calcitriol, and calcium or only calcitriol and calcium, those in the alendronate, calcitriol, and calcium group had significant improvements in spine and hip BMD, while BMD in the calcitriol and calcium group was stable [174]. In a randomized trial of long-term kidney-transplanted recipients that compared alendronate alone to alfacalcidol plus alendronate for 1 year, BMD improved at the spine and hip in both groups. However, the increase was only significant in the combination alendronate–alfacalcidol group, likely because of inadequate power in this small study [175]. While the results of the aforementioned studies are not uniform, the majority found that active vitamin D analogs when given alone or in combination with

**FIGURE 74.4** Comparison of mean ( $\pm$ SE) percent change in bone mineral density from baseline in cardiac transplant subjects treated with alendronate or calcitriol and untreated reference group. Adapted from Ref. [25].

bisphosphonates were effective for maintaining or improving BMD after transplant.

The major side effects of therapy with active vitamin D and analogs are hypercalcemia and hypercalciuria, which may develop at any time during the course of treatment, necessitating frequent urinary and serum monitoring. Additionally, concern has been raised about using very high single annual dose vitamin D (500,000 IU annually) and its impact on morbidity in terms of falls and fractures in the elderly [176]. Given the narrow therapeutic window with respect to hypercalcemia and hypercalciuria and monitoring requirements as well as the demonstrated efficacy of bisphosphonates to prevent posttransplantation bone loss [25,177], we believe these vitamin D analogs should be adjunctive rather than primary therapy for the prevention and treatment of transplantation osteoporosis.

It is important to test for and correct vitamin D deficiency before treating transplant candidates or recipients with IV bisphosphonates or denosumab. Bisphosphonates may not be optimally effective in the setting of vitamin D deficiency. Furthermore, intravenous bisphosphonate treatment has been reported to precipitate symptomatic hypocalcemia in patients with severe, unrecognized vitamin D deficiency [178]. Denosumab, a monoclonal antibody inhibiting RANK-L, blocks osteoclast activation and is commonly used to treat osteoporosis. Denosumab has shown great promise in reduction of both hip and nonvertebral fractures in postmenopausal women and BMD preservation in people with rheumatoid arthritis on high-dose glucocorticoids [155] but has not been widely studied in the solid organ transplant population. In one study of renal transplant recipients, denosumab increased BMD at the spine and hip when given every 6 months in the first year following transplant [179]. Analysis of microarchitectural changes in these patients using high-resolution peripheral quantitative CT (HR-pQCT) showed that there were increases in cortical thickness, bone stiffness, and failure load at the tibia in those randomized to denosumab, suggesting that both bone quality and BMD are improved with denosumab use in kidney transplant recipients at risk for osteoporosis [180]. A recent systematic review of four observational studies and the aforementioned clinical trial similarly reported increased BMD at the spine and hip with denosumab treatment [181]. Denosumab treatment is also associated with hypocalcemia in patients with severe vitamin D deficiency and inadequate calcium intake, and also in those with renal insufficiency despite calcium and vitamin D supplementation [180]. Denosumab also may be associated with increased infection risk, making it a potentially less ideal choice in those who are awaiting organ transplant and potentially already immunocompromised [155].

## 6. Conclusions

Vitamin D deficiency is extremely prevalent in patients with organ failure before transplantation and among transplant recipients. All patients should be assessed for vitamin D insufficiency and deficiency before transplantation and, if present, receive treatment. In addition, long-term transplant recipients should be monitored and treated for vitamin D deficiency in the context of broader management of bone disease. Pharmacologic doses of vitamin D and its analogs have utility after renal transplant but should be considered as adjunctive rather than primary therapy for osteoporosis in patients after solid organ transplantation. Treatment of vitamin D deficiency may improve skeletal health in transplant patients. The effects of vitamin D deficiency and in particular vitamin D supplementation on extra-skeletal morbidity after transplant are less clear. Additional interventional studies are needed to elucidate optimal repletion regimens after transplantation and to determine whether restoring 25(OH)D at the time of transplant reduces the development of infectious complications and immunosuppressant requirements.

## 7. Summary points

- Vitamin D plays a role in the regulation of immune cell proliferation, differentiation, and responsiveness; some evidence suggests a role of 1,25(OH)<sub>2</sub>D in prevention of graft rejection and opportunistic infections after transplantation.
- Vitamin D insufficiency and deficiency have been commonly described in patients with end-stage lung, liver, heart, and kidney disease prior to organ transplant.
- Vitamin D and its analogs may mitigate posttransplantation bone loss through several mechanisms including overcoming glucocorticoid-induced decreases in intestinal calcium absorption, reducing secondary hyperparathyroidism, and promoting differentiation of osteoblast precursors into mature cells.
- While the results of the current literature are not uniform, the majority of studies have found that active vitamin D analogs, given alone or in combination with bisphosphonates, maintain or improve BMD after transplant.

# Vitamin D, obesity, the metabolic syndrome and its sequelae

Barbara J. Boucher<sup>1</sup> and Elina Hyppönen<sup>2</sup>

<sup>1</sup>Queen Mary University of London, London, United Kingdom <sup>2</sup>Australian Centre for Precision Health, University of South Australia, Adelaide, SA, Australia

## OBJECTIVES

- To review evidence for lower vitamin D concentrations in obesity and to discuss how related differences arise.
- To review evidence for the efficacy of vitamin D supplementation in obesity and the implications of obesity for vitamin D requirement.
- To discuss obesity-related differences in vitamin D concentrations and the implications this can have on metabolic syndrome, related disorders, and other diseases.
- To consider the possible role of vitamin D on the risk of obesity.

## 1. Introduction

There is continuing interest in the role of adipose tissue in the determination of vitamin D status (serum 25-hydroxyvitamin D [25(OH)D] concentration) and of both vitamin D requirements and its bioavailability, because measures of human adiposity consistently relate inversely to serum 25(OH)D. Indeed, obesity was second only to low sun exposure as a predictor of the severity of vitamin D insufficiency (low serum 25(OH)D) in an earlier study [1,2]. The various mechanisms now thought to explain the increased risk of vitamin D deficiency found with obesity include both the dilution of vitamin D and of 25(OH)D into the

enlarged fat pool and the fact that the 25-hydroxylation of vitamin D by the liver has been shown to be reduced in obesity [3,4]. There is substantial variation in the estimated strength of this association among different population groups, which probably reflects methodological issues in the measurement of adiposity and the variations reported in measurements of 25(OH)D concentrations [5]. Also, similar body mass indices (BMIs) are found in different population groups despite markedly different ratios of visceral to subcutaneous fat deposition [6,7]. Such variations are important in assessing health risks as visceral adiposity is known to be a stronger risk factor than subcutaneous adiposity for the metabolic syndrome (MetS), type 2 diabetes mellitus (T2DM), and cardiovascular disease (CVD) [8,9].

Active hormonal vitamin D [1,25(OH)<sub>2</sub>D] has been shown, at both physiological and biochemical levels, to have mechanistic effects that counteract many ill effects of obesity and that reduce the risks of tissue damage seen with adiposity and in obesity-related metabolic disorders. Those data imply that ensuring adequate vitamin D nutrition in obesity should provide some protection against the adverse sequelae of obesity, including the various features of the MetS, which are more common in overweight and obese people than in slim people. This chapter, therefore, includes a brief overview of the demonstrable impacts of vitamin D on the disorders that comprise the metabolic syndrome and its sequelae and on inflammation, including the remote inflammatory tissue damage and increased cell senescence associated with obesity, especially relevant to atheromatous disease [10,11].

## 2. Adipose tissue as a vitamin D reserve

Adipose tissue was first proposed as a major storage site for vitamin D by Rosenstreich et al. [12]. This proposition was based on the fact that vitamin D is a fat-soluble vitamin, and on the measurements of tracer radioactivity contained in different vitamin D metabolites within the tissues and organs of weanling rats after they had been fed radiolabeled vitamin D<sub>3</sub> for 2 weeks. Vitamin D was found to be stored in its various forms, but intact (unaltered) vitamin D<sub>3</sub> was the principal form stored [12]. About 75% of intact vitamin D<sub>3</sub> in the human body is found in fat. For 25(OH)D, ~30% is present in the circulation, 20% in skeletal muscle, and 34% in adipose tissue [13]. Interestingly, adipose tissue is itself a site of vitamin D metabolism where both 25-hydroxylation and further 1 $\alpha$ -hydroxylation of 25(OH)D (via the enzyme 1 $\alpha$ -hydroxylase or CYP27B1) to form hormonally active 1,25(OH)<sub>2</sub>D take place, as does homeostatic catabolism of those metabolites via the enzyme 24-hydroxylase.

The amount of intact vitamin D in adipose tissue does not correlate with circulating cholecalciferol or 25(OH)D concentrations. Serum 25(OH)D concentrations do, however, correlate directly with those seen in both visceral and subcutaneous fat [14–16]. Wortsman, therefore, suggested that vitamin D is “sequestered” in adipose tissue, intact vitamin D passing into adipose tissue and being prevented from being further processed or passing back into the circulation [17]; a proposal based on finding of notably greater elevations of intact serum vitamin D<sub>3</sub> concentrations in normal than in obese people after exposure to ultraviolet B radiation [17]. However, another explanation is that serum 25(OH)D is lower in obesity because this metabolite simply spreads across the larger volumes of fat (volumetric dilution). This suggestion is supported by the fact that serum and adipose tissue 25(OH)D concentrations, but not cholecalciferol concentrations, are correlated across the life span. CYP27B1 concentration is lower in the white adipose tissue of obese versus slim people, likely reducing local vitamin D activation [18]. Differences in behaviors affecting vitamin D nutrition (such as habitual sun exposure, time spent outdoors, and choice of clothing) may also influence the contributions to serum 25(OH)D derived from the vitamin D synthesized in the skin in obese as compared with normal-weight individuals, though it is still unclear how vitamin D metabolites are handled once taken up by the adipose tissue.

1 $\alpha$ -Hydroxylase is present and active in adipocytes [19], but the “efficacy” of orally consumed vitamin D is reduced in obesity (i.e., it does not raise serum 25(OH)D concentrations as much). In addition, “deep” subcutaneous adipose tissue from obese subjects

contains less of both the vitamin D-activating enzymes than does “deep” subcutaneous fat of normal-weight subjects (by –71% for the vitamin D 25-hydroxylase and by –49% for 1 $\alpha$ -hydroxylase). Though the adipose tissue concentrations of both intact and 25-hydroxylated vitamin D are lower in fat from obese than from lean women, their 1,25(OH)<sub>2</sub>D concentrations are not different [20]. However, since serum 1,25(OH)<sub>2</sub>D is reduced in obesity, it could be that significant activation of vitamin D in adipose tissue compensates for the reduced 25(OH)D substrate availability from the serum [20].

Visceral and subcutaneous adipose tissues are not only metabolically “active” for vitamin D, but they also express the vitamin D receptor (VDR) that mediates both rapid nongenomic and slower genomic effects of 1,25(OH)<sub>2</sub>D through cell wall and nuclear vitamin D receptors (VDRs), respectively [21] (see Chapters 10–13). In addition, both these adipose tissues express the 24-hydroxylase enzyme that is catabolic for both 25(OH)D and 1,25(OH)<sub>2</sub>D [18]. Overall, therefore, the combined evidence suggests that adipose tissue can both synthesize and degrade vitamin D metabolites, thereby facilitating autocrine and paracrine effects on adipogenesis, lipid metabolism, and the regulation of inflammatory responses associated with obesity [21]. For a fuller description of vitamin D influences on energy homeostasis in adipose tissue, please see Chapter 28.

In addition to local intracrine effects, paracrine roles of 1,25(OH)<sub>2</sub>D in adipose tissue could contribute to, or account for, loss of 25(OH)D into fat, although a simple “dilution” effect could also occur [2]. According to the initial proposal by Rosenstreich [12], release of vitamin D metabolites from adipose tissue would be relatively slow, reducing potentially toxic effects of high dosages, yet allowing adipose tissue to act as a store in case of need. Such a system would contribute to the homeostasis of vitamin D activity, but other systems regulating skin synthesis of vitamin D and renal activation are likely to be more powerful in health. However, in starvation this mechanism may be important for the provision of vitamin D because marked weight loss does increase serum 25(OH)D concentrations [22], in the same way that marked weight loss is known to release other fat-soluble substances known to accumulate in fat, e.g., various toxic insecticides including DDT (dichlorodiphenyltrichloroethane) [23,24].

It is still uncertain whether adipose tissue uptake of vitamin D or its metabolites depends on its conventional association with vitamin D-binding proteins (DBPs), although DBP does carry 25(OH)D into renal cells for local activation to form hormonal 1,25(OH)<sub>2</sub>D (see Chapter 8). DBP knockout in rodents potentiates, but does not reduce, 1,25(OH)<sub>2</sub>D formation, suggesting

that unbound (“free”) 25(OH)D is important as a substrate for local tissue activation. The question of whether DBP binding of vitamin D metabolites such as 25(OH)D is necessary for its uptake by adipose tissues is important because, if free circulating 1,25(OH)<sub>2</sub>D is taken up, it would have the potential to help protect adipose tissue function despite the reductions in total serum 25(OH)D concentrations that are seen in obesity (see Chapter 7).

### 3. Obesity and vitamin D deficiency

It is well established from many metaanalyses that there is a higher prevalence of vitamin D deficiency (low serum concentrations of 25(OH)D) in those who are overweight or obese. Bidirectional Mendelian randomization (MR) data analysis has shown clearly that higher BMI leads to lower serum 25(OH)D concentrations but that linear reductions in 25(OH)D do not increase BMI [25]. Pereira-Santos et al. reviewed 23 studies and found a 35% increase in the prevalence of vitamin D deficiency for those classified as obese versus those of normal weight [26]. Similar rates of vitamin D deficiency in obesity were reported in children and adolescents (37%) as in adults (33%) [26]. Yao and colleagues [27] found 3.4 times greater odds of vitamin D deficiency for obese individuals compared with nonobese subjects, with similar findings reported by others [28,29]. However, with common outcomes, odds ratios tend to be inflated as compared with prevalence ratios and the metaanalyses mentioned before included studies with nonrandom population sampling, which often gave extremely high estimates; 5 of the 15 studies included in one metaanalysis having odds ratios >6, suggesting that estimates of effect size need review. Common to all metaanalyses assessing cross-sectional associations between obesity and vitamin D deficiency was considerable heterogeneity between the studies included. Furthermore, many used BMI as the primary indicator for adiposity, which, as already mentioned, is not a reliable measure of visceral adiposity. In addition, the associations between BMI and 25(OH)D are usually reported as being stronger in women than in men, probably reflecting gender differences in body composition as well as the inadequacy of BMI for assessing adiposity rather than any specific gender-related disorder of vitamin D metabolism in obesity. However, a small trial in overweight and prediabetic south Asian women supplemented at 60,000 IU weekly in milk for 8 weeks and followed for over a year showed reductions in truncal obesity with minimal reductions in glycemia [30]. The possibility that adipose tissue responses to vitamin D vary with ethnicity and/or gender should, therefore, be considered.

Despite some variations in their strength, inverse adiposity-25(OH)D associations have consistently been reported from studies in diverse age groups and from diverse geographical locations. These associations also appear to be present from infancy [31–33]. For example, higher circulating 25(OH)D values were reported with leaner body composition in 132 normal-term, nonobese, and breastfed babies aged from birth to 1 year old [31]. Correlations between adiposity and 25(OH)D have been reported at different ages and in populations of European, Asian, and African ancestry [26,32–34]. Geographical differences are also reported for the strength of those associations (e.g., stronger correlations between BMI and 25(OH)D for North Americans compared with European, and for Western as compared with Eastern countries [30,34,35]), which may reflect differences in the prevalence of obesity, and/or ethnic variations in fat distribution.

Another potential factor causing differences in the strength of the associations between adiposity and 25(OH)D is the prevalence rate for vitamin D deficiency. In the US National Health and Nutrition Examination Survey, for example, percentage body fat was more weakly associated with 25(OH)D concentrations in African Americans than in white American women [35], the authors suggesting this could reflect ethnic differences in adiposity–25(OH)D relationships, or the lower 25(OH)D concentrations in black versus white people that provide smaller reserves of this metabolite for distribution into adipose tissue. However, in that study body fat was measured by bioimpedance, which shows noticeable variations in precision of the estimates made for the different population groups [36], which could have contributed to the apparent differences. Such differences in association strength between studies or population groups may also reflect the lack of adjustment for the nonlinearity of these associations [37,38]. For example, in the 1958 British birth cohort (1958 BCE), a sample of white European-ancestry volunteers aged 45 years, the highest serum 25(OH)D concentrations were found with those of normal weight, with linear decreases with increasing overweight and obesity [38]. However, lower concentrations were also seen in participants who were notably underweight, which in this type of cross-sectional study may well have reflected the influence of reverse causality due to disease-related differences in vitamin D–relevant lifestyles, or requirements. Also, the similar nonlinear variations in 25(OH)D concentrations with adiposity that were found in the 1958 BCE whether adiposity was assessed using BMI or by waist circumference support the validity of this association [38] (Fig. 75.1).

The potential differences in 25(OH)D storage between different fat deposits remains unknown, but

**FIGURE 75.1** Variation in average serum 25(OH)D concentration by (A) body mass index (BMI) and (B) waist circumference in the 1958 British birth cohort (aged 45 year). Values are geometric means (95% confidence intervals) standardized by sex and season. Reproduced from Ref. [192] under the Creative Commons Attribution License.

observational data on associations between visceral/subcutaneous fat masses and serum 25(OH)D concentrations have shown that both central and visceral fat increases were associated with reductions in 25(OH)D in obese/overweight middle-aged adults but not with the increases in peripheral fat [39]. Andreozzi et al. found inverse correlations of waist circumference, and of waist/hip ratio with serum 25(OH)D [40]. A study in younger people (aged 6–18 years) also found adiposity associated inversely with serum 25(OH)D but showed no variation in that association with the different types of fat distribution [31], while studies continue to confirm visceral (central) adiposity as a better risk marker for

reduced vitamin D status than subcutaneous adiposity in adults [41].

#### 4. Obesity, DBP, and “free” vitamin D concentrations

The lower 25(OH)D concentrations seen in obesity imply “functional” vitamin D deficiency since it reduces 25(OH)D availability to target tissues. However, 99% of circulating 25(OH)D and of 1,25(OH)<sub>2</sub>D are bound to DBP or albumin (see Chapter 7). As with other hormone-binding proteins [42]. DBP concentrations

may, therefore, provide a reservoir of free 25(OH)D helping to regulate 25(OH)D bioavailability to target tissues and mean that the hormonal provision of 1,25(OH)<sub>2</sub>D within the target cells might be better supported by “free” 25(OH)D than by total 25(OH)D. However, until intracellular vitamin D metabolites can be quantified in cells *in vivo*, this remains in doubt. Renal and placental tissue access bound 25(OH)D by endocytic absorption of DBP through the actions of megalin and cubulin, not found in most other tissues [43]. Like total 25(OH)D, free serum 25(OH)D is inversely associated with weight in obesity. Vitamin D repletion has been suggested as a means of correcting, or at least improving, many different disorders, including the metabolic disorders associated with obesity where achieving repletion may require varying supplemental doses [44,45]. Some [46,47] but not all [48,49] studies suggest positive correlations between adiposity and DBP levels, and some studies also report reduced “free vitamin D” [free 25(OH)D] concentrations in obesity [46–50]. However, obesity’s effects on “free vitamin D” and whether free 25(OH)D affects bone health, or other health outcomes, remains in doubt.

## 5. The effect of weight loss on serum 25(OH)D concentrations

Since serum 25(OH)D values are lowered with increased adiposity, it is no surprise that weight loss, whether from dieting, or gastric banding, leads to rises in serum 25(OH)D [51,52]. Weight loss induces rises in serum 25(OH)D without increased expression of adipose 25-hydroxylase [2,18], making increases in adipose 25-hydroxyvitamin D production unlikely. Reversal of the hepatic reductions in 25(OH)D formation induced by obesity is a more likely explanation, though adipose CYP24A1 activity actually increases with weight loss [18] and reduced dilution into fat will also contribute. More recent NHANES data showed that weight loss of 5% over 5 or 10 years led to 25(OH)D rises of 5.5 and 5.1 nmol/L, respectively, in >6000 subjects [51]. In the heaviest people, serum 25(OH)D values were higher initially than in others, but concentrations did not rise with 5% or 10% weight loss, suggesting that intake levels may have been highest in the heaviest people. Despite the release of vitamin D and 25(OH)D into the circulation with weight reduction, this has not been reported to lead to toxic effects, no doubt because normal regulatory mechanisms continue to limit 1,25(OH)<sub>2</sub>D production (see Chapter 8 and 9). Additionally, there is longitudinal data to suggest that long-term changes in BMI predict changes in 25(OH)D concentration, so that vitamin D deficiency rates will fall in populations that achieve reductions in the prevalence of obesity, as was

seen prospectively in a subsample from the large Tromsø study [39], where participants with at least a one-unit reduction in BMI during the 14 years of follow-up averaged a 4.5 nmol/L increase in 25(OH)D concentration while those who gained weight averaged a reduction in serum 25(OH)D of –2.5 nmol/L. Some support for increases in 25(OH)D with weight loss comes from a systematic review of weight reduction trials in obesity [2,22]. One metaanalysis showed variable increases in serum 25(OH)D in 18 of 23 included trials, while metaregression analysis suggested an increase of 6 nmol/L in serum 25(OH)D for each 10 kg weight loss, while each 10% loss of fat mass was followed by an increase in serum 25(OH)D of 9 nmol/L [2]. Such findings have been supported by other similar studies though the changes were small and showed no suggestion of a dose–response relation [51].

It is likely that the quantity of 25(OH)D “released” with weight loss will vary with the proportion of fat loss from each type of fat store. Visceral adipose tissue regularly contains ~20% more cholecalciferol than subcutaneous fat so that reductions in visceral adiposity should increase serum 25(OH)D concentrations more than reductions in peripheral adiposity. In one lifestyle intervention trial in viscerally obese men, decreases in intraabdominal fat mass did have the highest impact on 25(OH)D outcomes, a 50% reduction in visceral fat being accompanied by a 27% rise in serum 25(OH)D concentrations [51]. That study further suggested that central fat loss achieved those increases in serum 25(OH)D concentrations in the absence of any changes in dietary vitamin D intake or in the use of vitamin D supplements. Studies of weight reduction through surgical intervention often include patients with quite low baseline 25(OH)D concentrations [52–54]. Major bariatric surgery, e.g., with gut bypass, often leads to long-term fat malabsorption, making correction of vitamin D deficiency difficult and the routine management of patients after bariatric surgery includes long-term vitamin D supplementation, though achieving 25(OH)D concentrations at or above 75 nmol/L is often difficult [54,55]. Current guidance from the European Calcified Tissue Society (ECTS) states that postbariatric surgery patients should be adequately provided with vitamin D before other bone-protective measures are introduced, that this advice should be kept under review, and that adjusting vitamin D intakes to individual need in such patients should be included in routine clinical management [56].

## 6. Can vitamin D supplementation prevent, or reduce, obesity?

Evidence available to date suggests that 1,25(OH)<sub>2</sub>D production in human adipose tissue is likely to be

homeostatically regulated, as it is in other target tissues, independent of parathyroid hormone. In addition, adipocyte maturation from preadipocytes is inhibited by  $1,25(\text{OH})_2\text{D}$  [57]. Thus, vitamin D adequacy should help to inhibit the enlargement of developing fat masses in early life, though it is not thought likely to reduce adult fat masses. In utero epigenetic effects resulting from lack of maternal vitamin D are, however, associated with increased obesity in childhood [58]. At a physiological level, there is evidence to suggest that the specific effects of  $1,25(\text{OH})_2\text{D}$  on adipose tissue could be protective for obesity because it increases lipolysis, reduces the lipid content of differentiated 3T3-L1' adipocytes, and reduces expression and activity of adipogenic genes while increasing expression of lipolytic genes and of NAD-SIRT-1 pathway activity [59–61], these effects being suggestive of a calorie-consuming response. Though obesity may not affect calcium-sensing receptor gene expression in white adipose tissue [59–61], vitamin D increases mature adipocyte apoptosis; this is affected through rapid nongenomic increases in intracellular calcium following cell wall caveolar VDR activation rather than resulting from activation of the nuclear VDR pathway [61] (see Chapters 10–13).

Despite such mechanistic evidence, RCTs assessing the effects of vitamin D supplementation have not provided convincing evidence of an effect of vitamin D on adiposity or adiposity indices in adult obesity. Some treatment effects have been reported, mainly from studies using vitamin D plus calcium. The largest of these studies is the Women's Health Initiative (WHI), which was a randomized double-blinded placebo-controlled trial performed in a cohort of 36,282 postmenopausal women that compared the daily dosage of 400 IU vitamin  $\text{D}_3$  (+1000 mg calcium) with placebo [62]. This WHI study reported a small reduction in weight gained during the 7-year trial of supplementation as compared with weight gained on the placebo, with an average difference of  $-130$  g. However, the evidence for differences in weight change was only seen in women who had baseline calcium intakes that were below the recommended dietary intake (DRI) of  $>1200$  mg/day, while no such effect was seen in women regularly consuming dietary calcium at, or above, the DRI for calcium [62]. Due to the design of that study, it was not possible to establish any definite independent effects of supplemental vitamin D from effects of supplemental calcium. However, given that the finding of reduced weight gain was dependent on baseline calcium intakes, the very small vitamin  $\text{D}_3$  dosages given, and that participants were also free to consume up to 1000 IU of vitamin D as part of their self-supplementation, it is unlikely that reduced weight gain resulted from the vitamin D component of the treatment regimen in that particular study.

Later, metaanalyses of available RCTs [63,64] also failed to provide evidence for weight reduction or changes in adiposity indices. However, these did allow for the evaluation of the effects of vitamin D supplementation,  $+/-$  = calcium versus placebo, and by vitamin D + calcium versus calcium alone. These metaanalyses identified no independent effects of vitamin D or evidence for a dose–response effects of supplemental vitamin D on adiposity [63] though some studies have suggested a reduction in visceral obesity [65].

Although the available evidence does not support any major effect of vitamin D supplementation on weight change or BMI in adults, there are still relatively few studies, which have investigated the effects of vitamin D supplementation on specific areas of fat tissue deposition in obesity. Potential benefits were suggested by two double-blind parallel trials providing vitamin D in fortified orange juice, one using regular orange juice and the other using low-calorie (50% reduced energy) orange juice to compare intakes of vitamin  $\text{D}_3$  (at 300 IU (7.5 mg))/day + calcium (1050 mg/day), against nonfortified juices [65]. Fortification led to some reduction in visceral adiposity in both trials but without changes in total body weight, BMI, or waist circumference. These last two trial results are of interest, but in no trial giving calcium and vitamin D can the effects of vitamin D be clearly disentangled from those of calcium. Genetic variations in the vitamin D axis may also affect responses to supplementation as suggested by an RCT in vitamin D–deficient subjects with T2DM, where central obesity was reduced most markedly in subjects with the VDR-Cdx-2 genotype [66].

The potential causal effect of higher serum  $25(\text{OH})\text{D}$  in regard to a lower BMI has also been investigated in genetic epidemiological studies, which have used genetic markers affecting substrate availability (*DHCR7*) or  $25(\text{OH})\text{D}$  synthesis (*CYP2R1*) to reflect differences in serum  $25(\text{OH})\text{D}$  concentrations [67]. However, rather than providing evidence in support of the causality of higher  $25(\text{OH})\text{D}$  concentrations as a determinant of lower BMI, these studies have consistently suggested that the observed correlations are driven by higher BMIs, leading to lower  $25(\text{OH})\text{D}$  concentrations [25,68]. One caveat with this type of genetic epidemiological, Mendelian randomization (MR), study, as well as with clinical trials of vitamin D supplementation conducted to date, relates to the lack of information specific for individuals who are clinically vitamin D deficient. Thus, even if vitamin D supplementation of general populations is not likely to influence weight regulation, from studies published to date, it is still not possible to fully exclude a possible causal influence on adipose tissue metabolism, or on obesity prevention, of corrective vitamin D prophylaxis in overtly vitamin D–deficient individuals [25], though this may be clarified if future

MR studies can use nonlinear analytical methodology (see Chapter 61 for further information).

It is of interest that even in a trial just published on the effects of supplementation on obesity in older adults (>65 years old and with concomitant calcium supplementation) who had baseline serum 25(OH)Ds of 10–30 ng/mL and where the average doses given were ~3750 IU/day, achieved serum 25(OH)D concentrations were not reported even though other work has shown it can take much higher doses of vitamin D to achieve repletion in obesity than in the nonobese [69] (see the next section).

## 7. Obesity and the efficacy of oral vitamin D supplementation

Responses of serum 25(OH)D concentration to vitamin D supplementation with specific doses are three to four times higher in some trials than others [70]. Differences in adiposity/body weight account for some of this between-study variation in response since obese individuals require larger doses of vitamin D than lean subjects to achieve equivalent 25(OH)D concentrations. Gallagher and colleagues, for example, tested seven doses of vitamin D, increasing from 400 to 4800 IU/day, and compared final serum 25(OH)D values after supplementation in normal-weight, overweight, and obese women [71]. That trial showed that the response

to supplementation across all dosages was notably greater in normal weight (BMI <25) compared with obese women [71]. However, despite consistently lower responses in the obese compared with normal-weight participants, there was no evidence for any dose–response effects in the variation in 25(OH)D responses with increasing severity of overweight or obesity (Fig. 75.2). In addition, Heaney et al. [72] showed that fat mass was not superior to weight in predicting 25(OH)D responses to supplementation, which suggests that both adipose tissue and skeletal muscle provide significant storage for 25(OH)D (see Chapter 29).

Based on comprehensive systematic review and metaanalyses, Zitterman et al. combined data from 94 independent trials and demonstrated a nonlinear logarithmic association between daily vitamin D dose (per kg total body weight) and the resultant increase in serum 25(OH)D concentrations [73]. In addition to body weight, they identified age as a key predictor for the response to supplementation; in their evidence synthesis, the trials in older people typically reported greater increments in serum 25(OH)D compared with the trials in younger people. This may be due to higher baseline 25(OH)D concentrations in younger people, although the authors suggested that these differences may, in part, reflect age-related changes in calcium and vitamin D physiology [73]. One of the stated aims of that report by Zitterman and colleagues was to develop a formula to establish vitamin D dosages required to

**FIGURE 75.2** The effect of body mass index (BMI) on response to vitamin D supplementation at different dosages. *Reproduced from Ref. [71].*

reach certain target 25(OH)D concentrations in people of different sizes. Fig. 75.2 [73] shows the predictions for the incremental vitamin D dosages required by vitamin D-deficient individuals weighing 50, 75, and 100 kg to reach an adequacy status defined by endpoint 25(OH)D concentrations of either  $>50\text{ nmol/L}$  or  $>75\text{ nmol/L}$ . There are other vitamin D dose prediction formulae giving slightly different estimations. Drincic and colleagues [74] used data from a group of clinically obese (BMI 30–58), but largely vitamin D-replete individuals with an average baseline 25(OH)D value of  $58\text{ nmol/L}$ , and developed a predictive equation based on studies using relatively high vitamin D intakes (at 1000 IU/d, 5000 IU/d, and 10,000 IU/d). According to their formula, the supplemental daily vitamin D<sub>3</sub> doses to give (in IU/d) can be estimated as  $[(\text{weight (kg)} \times \text{desired change in 25(OH)D (in nanograms per milliliter)} \times 2.5)] - 10$  [74]; based on this estimation, the predicted dosages required are notably higher. For example, for a  $25\text{-nmol/L}$  increase in serum 25(OH)D in an individual weighing 75 kg, a dosage of 1865 IU/day is suggested.

Ekwaru and colleagues [75] used information from a large community sample with 22,214 cross-sectional assessments of serum 25(OH)D to estimate the dose-response relationship between oral vitamin D supplementation and achieved 25(OH)D concentrations; the sample was derived from a database including volunteers taking part in a preventative health program, with an emphasis on providing advice in relation to vitamin D supplementation. In this group, participants were self-supplementing with up to 50,000 IU of vitamin D per day, and the baseline 25(OH)D concentrations were also relatively high ( $90.5\text{ nmol/L}$ ). The estimated response to supplementation showed an exponential pattern, with noticeably greater increases in serum 25(OH)D seen in response to smaller as compared with higher dosages. However, in this group, where vitamin D intakes and 25(OH)D concentrations were higher than in most other study populations, 25(OH)D concentrations were again found to be lowest in those individuals who were obese or overweight, as were the increases associated with supplementation. Based on these data, the authors recommended that supplemental vitamin D intakes for obese individuals should be two to three times higher than for those of normal weight, and 1.5 times higher for overweight individuals [75]. Another study in obese individuals (BMI  $>30$ ), which had treated all participants to have serum concentrations at  $\sim 34.0\text{ ng/mL}$  ( $84\text{ nmol/L}$ ) before dividing them into different treatment groups, found that intakes of 2000 IU/day were not enough to retain concentrations at this level over 6 months, while in the group receiving 125 IU/kg/day, the levels remained stable [76].

A retrospective chart review of obese male and female adolescents with vitamin D insufficiency (25(OH)D  $20\text{--}30\text{ ng/mL}$ ) suggested that treatment with 800 IU/day was not enough to increase and retain concentrations  $>30\text{ ng/mL}$  [77]. This study also reviewed adolescents with vitamin D deficiency ( $<20\text{ ng/mL}$ ) who had received a weekly dose of 50,000 IU over 6–8 weeks, which was sufficient to raise average concentrations from  $16\text{ ng/mL}$  to  $23\text{ ng/mL}$ , with 28% reaching  $>30\text{ ng/mL}$ . This fits with the limited data available from studies in children and adolescents, which suggest poor 25(OH)D responses to supplementation in obesity [78]. In those aged 12–18 years, for example, rises in serum 25(OH)D with vitamin D at 2000 IU/day were  $\sim 2$  times greater in normal weight than in obese subjects [78], suggesting that supplemental vitamin D requirements for obese as compared with normal-weight children should be doubled, much as is suggested for adults. Small, but significant, increases in total serum calcium concentrations were seen, without any adverse effects, in the normal weight but not the obese children taking 2000 IU/day, a finding suggesting that body weight should be allowed for when supplementing children with vitamin D in amounts above the currently recommended daily intakes for children, as is standard practice when prescribing medication for children.

## 8. Brown adipose tissue, obesity, and vitamin D

Brown adipose tissue is prominent in hibernating animals, generating heat from fatty acid oxidation and increased uncoupling protein-1 (UCP-1) activity. While brown adipose tissue was long thought to be active only in early life in humans, it is now known that “beige” adipocytes remain in place in various sites and develop brown adipocyte functions under cold or other types of stress [79]. Both brown and white adipose tissue generate proinflammatory cytokines [80], which must increase obesity-related health risks. Brown adipose tissue deposits form during human embryogenesis from precursor cells that also form myocytes (induced by the “myogenic factor 5 promoter”). This effect increases with high-physiological levels of  $1,25(\text{OH})_2\text{D}$  [81] and likely contributes to the recovery of muscle strength with timely correction of vitamin D deficiency, since skeletal muscle atrophy with adipocyte infiltration is a feature of chronic vitamin D deficiency. It is also likely to contribute to the improved myocardial function seen with correction of deficiency in heart failure [82,83].

Adipose tissue UCP-1 expression is inhibited by VDR binding to negative-response elements in the UCP-1

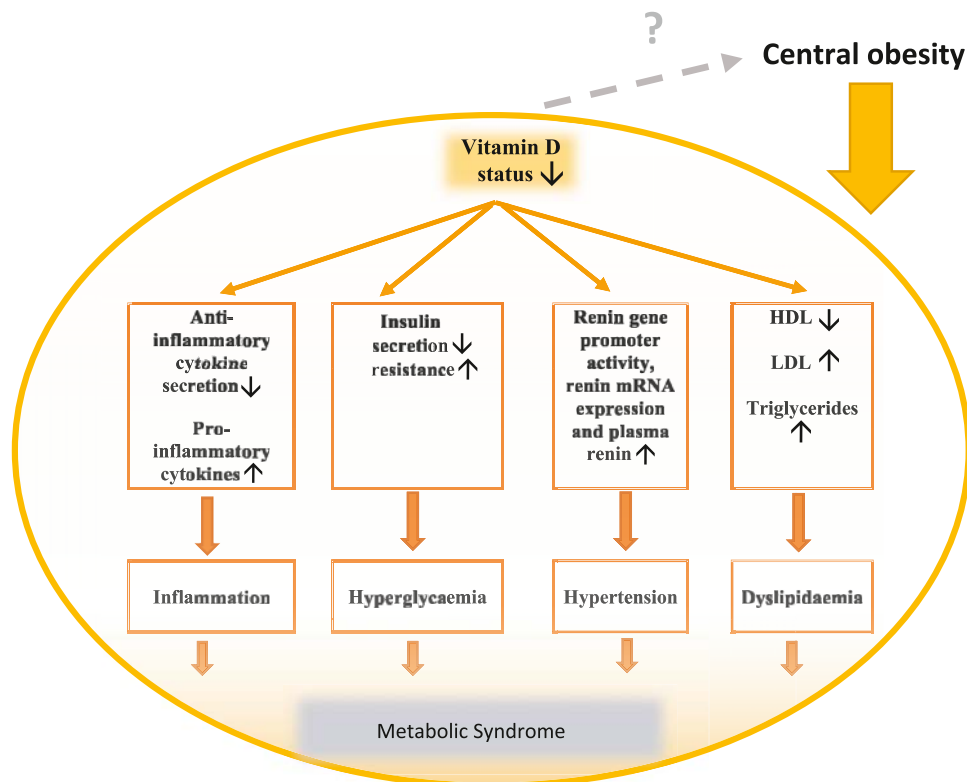

gene promoter region, and  $1,25(\text{OH})_2\text{D}$  suppresses brown adipose tissue differentiation, dose-wise [80,81]. Thus, defects in the VDR and lack of vitamin D can increase the “browning” of human white adipose tissue. Specific adipose tissue VDR knockout (VDR-KO) has, therefore, been suggested as a potential measure for increasing energy expenditure to assist in weight loss [79,82,84,85].

Sizable brown adipose tissue deposits in newborn humans provide valuable thermogenesis but become minimal in adults and show seasonal variation with increases in winter, likely because VDR activation by activated vitamin D suppresses brown fat activity and serum  $25(\text{OH})\text{D}$  normally increases in the summer [86,87]. Increasing brown adipose tissue formation, which could increase energy expenditure has, as mentioned before, been considered as a potential treatment for obesity. However, while brown adipose tissue is scattered throughout white adipose tissue in ~10% of normal children under 10 years old, this is not usually seen in later childhood or in adult obesity, though beige fat deposits persist in adults [79,88]. Hence, ways to promote browning of adipose tissue generally might need to begin in early childhood, while targeted activation of beige fat could increase energy consumption at any age.

## 9. Obesity, vitamin D, and metabolic syndrome

In brief, cross-sectional and prospective associations between vitamin D nutrition and metabolic syndrome (MetS) are well known, and low serum  $25(\text{OH})\text{D}$ s are also related dose-wise to increased risks of MetS, T2DM, and CVD prospectively [89–93] (see Chapter 26). Vitamin D nutrition has mechanistic effects protective against MetS disorders through direct and indirect effects, many contributing directly to the disorders associated with obesity (Fig. 75.3).

Adipose-specific VDR-KO in mice causes increased growth rates and increases visceral adiposity, mainly in females, with its associated adverse effects on health [90,91,94,95]. There is also some evidence suggesting greater reductions in serum  $25(\text{OH})\text{D}$  with visceral than subcutaneous adiposity, but with reductions in insulin resistance and inflammation in obesity with higher vitamin D status [95–98]. Since vitamin D deficiency appears to increase the risks of MetS abnormalities, T2DM and CVD, adequate vitamin D status should reduce obesity-related health risks even without weight loss. Clinical studies aiming to establish causality for the effect of increasing  $25(\text{OH})\text{D}$  concentrations and MetS abnormalities, CVD and T2DM have typically provided little evidence for an effect. This may be due to a

**FIGURE 75.3** Conceptual framework for the proposed joint effects of central obesity and low vitamin D status on the aggravation of metabolic abnormalities and disease risk. CVD, cardiovascular disease; NAFLD, nonalcoholic fatty disease of the liver; T2DM, Type 2 Diabetes mellitus.

combination of increases in 25(OH)D being diluted into the enlarged fat mass, combined with reduced synthesis of 25(OH)D in obesity that is due to suppression of the hepatic 25-hydroxylase enzyme [3,4]. While it has been suggested that the association between vitamin D and cardiovascular risk is merely due to confounding [99], at the physiological and biochemical level, there is compelling mechanistic evidence showing that 1,25(OH)<sub>2</sub>D inhibits many of the adverse effects of an enlarged fat mass.

Most clinical trials to date have been of relatively short duration and could well have failed to include individuals with vitamin D deficiency and/or patients in the earliest stages of the metabolic syndrome. Furthermore, many such studies gave calcium supplementation with vitamin D and accepted relatively high, but unknown, amounts of personal vitamin D intakes in both test and control arms during trials. Overall, the known mechanisms of action of vitamin D demonstrate the potential for adequate provision of vitamin D to reduce the severity of the disorders and health risks commonly seen in association with obesity including the other metabolic syndrome disorders. Although marked weight loss can reduce blood pressure, dyslipidemia, and hyperglycemia, often to normal, it is not easy to achieve, nor is it easy to disentangle the effects of inadequate vitamin D repletion from those of obesity in practice [100].

Prospectively, there are lower overall risks of incident metabolic syndrome and of T2DM after 10 years of follow-up in those with higher baseline vitamin D status compared with those with lower baseline status (e.g., 93). Evidence continues to accumulate to show that better provision of vitamin D reduces abnormal insulin resistance, a recognized risk marker of increased risks of both T2DM and CVD, as well as promoting glucose homeostasis. Problems with randomized control trial (RCT) design continue to reduce the chance of their providing definitive findings [100]. One would, however, predict that optimal vitamin D status should be protective against T2DM as recently reported among those with prediabetes [45] and against CVD from the reported mechanistic effects.

In addition, genetic evidence from MR studies support possible benefits from lifelong increases in serum 25(OH)D with respect to lower risks of T2DM, CVD, and MetS [68,101,102]. Recent findings using a novel nonlinear design, which allows researchers to examine the effects of increasing 25(OH)D concentrations in the context of vitamin D deficiency, suggested notable benefits with respect to lower blood pressure and for CVD risk with increases in serum 25(OH)D up to ~50 nmol/L, with little changes with further increases in 25(OH)D concentrations above ~50 nmol/L [101]. Since all nutrient effects, including health effects of

vitamin D, demonstrate threshold behavior, nonlinear methodology gets around the usual problems in conventional MR analyses that arise from the often false assumption of linearity of association (i.e., that higher 25(OH)D values have quantitatively similar effects regardless of the vitamin D status of the individual) [103] (see Chapter 61). There have been many reports of associations of vitamin D deficiency with risk of MetS over many decades [105–107] and, in view of the increased mortality associated with obesity and type 2 diabetes, mainly from cardiovascular disease, clarification of the contribution of risk from vitamin D deficiency as compared with that due solely to obesity is badly needed.

## 9.1 Inflammation and hormonal adipokines

The adverse remote effects of obesity result largely from the secretion of adipokines and of proinflammatory cytokines and hormonal factors. The overall immunomodulatory effects of 1,25(OH)<sub>2</sub>D lead to reduction of tissue damage from severe innate immune responses and from prolonged adaptive (acquired) immune responses. 1,25(OH)<sub>2</sub>D suppresses proinflammatory factor secretion and concomitantly promotes the secretion of antiinflammatory cytokines [97,108–112]. Particularly relevant to obesity is the reduction by 1,25(OH)<sub>2</sub>D of proinflammatory cytokine secretion by the large accumulations of macrophages that develop in the enlarged visceral fat deposits and that are known to induce remote inflammatory effects in other tissue including the vasculature and nervous system [111]. Such benefits are mediated, in part by suppression of the NF- $\kappa$ B pathway, leading to reduction in the secretion of proinflammatory cytokines such as IL-6 [111,112]; indeed, many genes are well known to be modulated through VDREs on their promoter regions [113]. Macrophage-derived cytokines upregulate the VDR as well as inducing inflammation, providing the opportunity for feedback regulation that would tend to reduce obesity-induced inflammatory tissue damage in vitamin D adequacy; however, information on whether supplementation does provide clinical benefits in obesity, and what vitamin D intakes and serum 25(OH)D values are necessary for optimal health benefit in obesity remains unclear [114].

Since inflammation is seen in adipose tissue and has major remote effects increasing CVD and T2DM risks, the analysis of UK biobank data using the nonlinear MR methodology that has revealed reductions in CVD risks with genetically determined increases in serum 25(OH)D among those with vitamin D inadequacy at baseline is of current interest [101]. A recent study has provided further direct evidence for a causal link

between vitamin D deficiency and increased inflammatory atherosclerosis [115]. Furthermore, bidirectional MR analysis has recently shown sharp decreases in serum CRP levels with increases in genetically determined 25(OH)D levels that are inversely associated with serum 25(OH)D at values < 25 nmol/L and with a similar, but less marked, association in subjects with insufficiency (25(OH)D values between 25 and 50 nmol/L), but no association at values > 50 nmol/L [116]. This suggests that correction of vitamin D deficiency can help reduce systemic low-grade inflammation, potentially mitigating obesity-related health risks including cardiovascular disease [116].

Adipokines produced by adipose tissue have variable effects, leptin and adiponectin improving insulin sensitivity while others increase the risk of glucose intolerance and of the metabolic syndrome in general [117]. Adipose tissue macrophages also secrete cytokines such as TNF- $\alpha$  and IL-6, which contribute to worsening adiposity-associated inflammation remotely, as in atherosclerosis, as discussed before. Metaanalysis of RCTs has not suggested an overall effect of vitamin D supplementation on serum leptin concentrations, but correlations are common between changes in leptin and in 25(OH)D concentrations. Leptin, a circadian appetite suppressant secreted by adipose tissue, reduces food intake and body weight but is not used to control obesity, though potential ways to exploit its effects remain of interest [118].

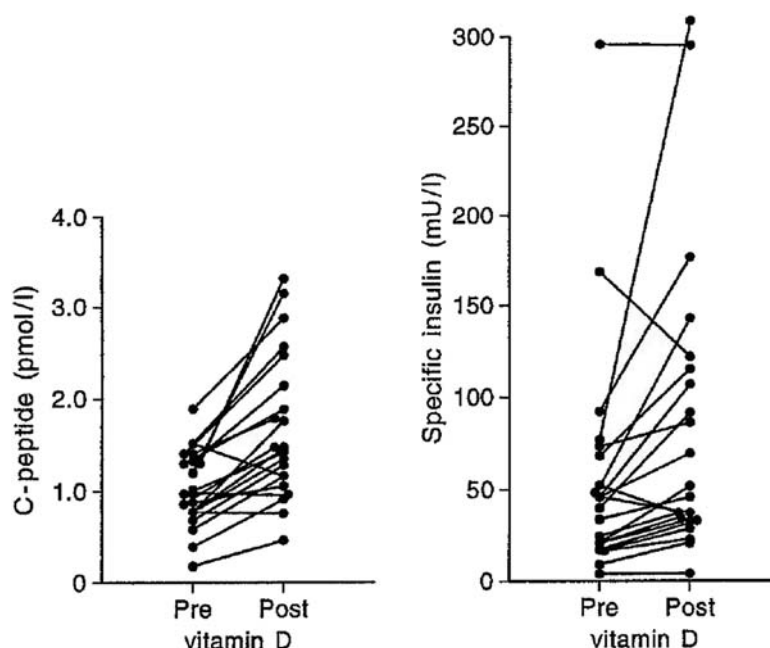

Cord blood leptin is raised in gestational diabetes but inversely associated with cord blood adiponectin, which is associated with neonatal adiposity [118,119]. Similarly in adults, circulating concentrations of adiponectin also relate inversely to obesity and directly to serum 25(OH)D with genetic evidence for a causal association; 1,25(OH)<sub>2</sub>D stimulation of adiponectin secretion [120,121] should reduce insulin resistance and MetS and T2DM risks since review of the literature shows that adiponectin increases tissue glucose uptake and fatty acid oxidation, thereby increasing insulin sensitivity in liver and muscle [120]. Despite this, RCTs report no increases in plasma total adiponectin concentrations with vitamin D supplementation [121] though many were small (only one included >100 participants), of short duration, and with limited data on adipokine profiles. One exception was the auxiliary study to the Vitamin D Assessment (ViDA) study, giving 2000 IU/day of vitamin D (vs. placebo) during lifestyle-based weight loss over 1 year [122], which did not find improvements in the eight inflammatory biomarkers studied (or in their composite score). A secondary stratified analysis, however, looking solely at those who lost weight, suggested that those taking vitamin D had greater reductions in circulating IL-6 (but not of other cytokines) versus those on placebo [122].

From intrauterine life onward, insulin-like growth factor (IGF-1) and its binding proteins (IGF-1BPs) are secreted by adipose tissue, including preadipocytes [123], and have some effects on adipose tissue development and also reduce insulin resistance (IR) through their effects on liver and muscle. Serum IGF-1 concentration associates inversely with MetS risk in the vitamin D-replete subjects among the ~6800 people being followed in the 1958 BCE, aged 45 years [38]. This is of interest since 1,25(OH)<sub>2</sub>D upregulates IGF-1 secretion, and IGF-1 upregulates vitamin D activation, a feedback cycle likely to enhance the efficacy of both IGF-1 and vitamin D [124].

## 9.2 Insulin resistance, insulin secretion, and glycemia

Increased insulin resistance (IR) develops in obesity where increased adiposity of both liver and muscle is usual. Vitamin D has been known for ~40 years to be necessary for normal insulin responses to glucose [125–127]. Insulin release from storage granules in healthy islet beta cells results from rapid nongenomic effects increasing intracellular calcium content (phase 1) following VDR activation in islet beta cell wall caveolae by 1,25(OH)<sub>2</sub>D. This effect is followed by slower genomic effects increasing insulin synthesis that follow 1,25(OH)<sub>2</sub>D activation of nuclear VDRs (phase 2) [125,126], which depends on dietary vitamin D in isolated rat islets experimentally [125–127]. Long-term increases in IR eventually lead to the well-known beta-cell failure, beta cell death, and islet fibrosis that eventually cause overt T2DM.

Protective effects of vitamin D against T2DM should, therefore, be the greatest before irreversible pancreatic islet damage develops, a postulate supported by the dose-wise reductions in MetS and in T2DM risks seen prospectively with higher baseline vitamin D status after 10 years [91,92]. Further support comes from the finding that glucose-stimulated secretion of insulin (GSSI) with vitamin D supplementation was greater, as a dose-effect, in T2DM subjects with shorter durations of T2DM [128]. These various data suggest that early vitamin D repletion should maximize risk reduction for T2DM. The need to establish vitamin D repletion early for reducing T2DM risks was also suggested by the finding of larger increases in 30 min GSSI on oral glucose tolerance testing in those with the higher, and thus the most normal, GSSI responses presupplementation [129] (Fig. 75.4). The total reversal of new-onset glucose intolerance in renal failure by 1,25(OH)<sub>2</sub>D treatment also supports the concept that the earlier the correction of vitamin D deficiency, the more likely the reduction in the risks of hyperglycaemia and type 2

**FIGURE 75.4** Individual changes in C-peptide and specific insulin (30 min OGTT concentrations) before and after vitamin D administration in 22 individuals "at-risk" of diabetes (spot blood glucose  $>6$  mmol/L less than 2 h after food or  $>4.6$  mmol/L more than 2 h after food). Reproduced from Ref. [129].

diabetes [130]. Additionally,  $1,25(\text{OH})_2\text{D}$  is protective against UCP-2 overactivity-induced apoptosis of pancreatic islet cells, and against hyperglycemia-induced renin–angiotensin–system overactivity, functions protective for islet beta cells as hyperglycemia develops [131].

RCTs with adequate vitamin D supplementation can reduce abnormally raised insulin resistance, and T2DM risk in those with prediabetes (e.g., [45]) although these benefits of better D status have not yet been confirmed in obesity and require further study. Vitamin D reduces hepatic lipid formation and glucose output under insulin-resistant conditions experimentally [132], but RCTs do not always reproduce these effects, probably due to inadequate numbers of deficient subjects recruited and inadequate supplementation to correct those with deficiency [133]. Informatively, a study in 81 vitamin D–deficient insulin resistant, but normoglycemic, South Asian women in New Zealand given 4000 IU/day for at least 6 months showed significant improvements in insulin sensitivity and falls in IR (with no changes in C-peptide or glycemia), which only appeared when serum  $25(\text{OH})\text{D}$  concentrations reached 80–119 nmol/L [105], a finding suggestive of a threshold effect at  $\sim 80$  nmol/L. This is in line with cross-sectional data on 239 obese black and white women without diabetes, whose indices for glycemia and IR were minimal with serum  $25(\text{OH})\text{D}$  values  $\geq 65$  nmol/L [134].

### 9.3 Vitamin D and hypertension

Since hypertension aggravates cardiovascular disease (see Chapter 26) and is itself aggravated by obesity, and since it contributes to the ill health associated with obesity and the metabolic syndrome, the question as to whether vitamin D repletion can reduce the blood pressure in hypertensive patients is of importance. As discussed earlier, renin secretion is suppressed by  $1,25(\text{OH})_2\text{D}$  and knockout of the vitamin D receptor increases systolic blood pressure [135,136]. Despite these mechanistic effects, many trials of vitamin D supplementation in hypertension have failed to reduce the blood pressure [137]. However, typically, such trials have been conducted in individuals who are relatively vitamin D replete, while MR evidence suggests that the association may be causal and also suggests that benefits may be largely restricted to the correction of deficiency [101,138]. In Fig. 75.5, we show how increases in  $25(\text{OH})\text{D}$  concentrations associate with lowering of systolic blood pressure in participants who have concentrations below 25 nmol/L (as compared with being at or above 50 nmol/L), and how this association plateaus above 50 nmol/L [101]. This finding is in line with an earlier linear MR study that has already provided genetic evidence for a causal effect of higher  $25(\text{OH})\text{D}$  with both a lower blood pressure and with reductions in the risk of hypertension [138]. Thus, the increased CVD risk due to concomitant hypertension in obesity should be reduced if vitamin D deficiency can be

**FIGURE 75.5** Genetic association of serum 25-hydroxyvitamin D with systolic blood pressure. The dot represents the reference point of serum 25-hydroxyvitamin D of 50 nmol/L. The shaded areas represent the 95% confidence intervals. Adjustment includes age, sex, assessment centre, birth location, single nucleotide polymorphism array, Top 40 genetic principal components, and nuisance factors which could affect serum 25-hydroxyvitamin D measurements, including month in which blood sample was taken, fasting time before blood sample was taken, and sample aliquots for measurement. *Reproduced from Ref. [101].*

avoided over time. Interestingly, reductions in blood pressure and in CVD risks have now been reported by secondary MR analysis in subjects with both diabetes and hypertension [139].

#### 9.4 Dyslipidemia and nonalcoholic fatty disease of the liver

Fatty acids formed specifically in the white adipose tissue are increased in length by fatty acid elongases, and one of these (Elovl3) is downregulated by 1,25(OH)<sub>2</sub>D through negative-response elements in the promoter region of its gene [140]. Inverse associations of vitamin D status with the severity of nonalcoholic fatty disease of the liver (NAFLD) are widely reported, and with its serious sequelae of cirrhosis and primary liver cancer [141,142], though not in a study of obese children under 18 years, apart from the evidence of hepatic inflammation [143]. In high-fat:high-glucose diet-fed rodents and in hepatocytes, *in vitro*, 1,25(OH)<sub>2</sub>D has been shown to promote hepatic lipid homeostasis by increasing free fatty acid metabolism, thereby reducing hepatic TAG formation and hepatic steatosis, and to reduce hepatic glucose output [132]. These effects could help to explain why increased severity of steatosis and other features of NAFLD are reported with lower serum 25(OH)D concentrations [141–147]. In a recent systematic review and metaanalysis, an RCT was mentioned in 60 patients with NAFLD, given 50,000 IU vitamin D<sub>3</sub> weekly for 10 weeks versus placebo; mean serum

25(OH)D rose significantly on vitamin D (to 70 nmol/L), with a concomitant fall in IR (estimated as homeostatic model assessment HOMA-IR) [148]. In the controls, there was also a small rise in 25(OH)D, and though there was no change in estimated insulin secretory response to glucose (HOMA-beta) in controls, there was a small fall in fasting glucose, suggesting that this is a consistent effect. However, the inverse dose-dependent relationship between vitamin D status and NAFLD has also been found in vitamin D repletion suggesting some degree of reverse causality in this association as would be expected with hepatocellular disease since the liver is a major site of vitamin D 25-hydroxylation. These data are suggestive of potential benefits of giving vitamin D therapeutically in NAFLD. The aforementioned review and metaanalysis of data from 16 trials of vitamin D supplementation in NAFLD has shown that supplementation increased serum HDL cholesterol, reduced body weight and BMI, waist circumference, serum alanine-transferase, HOMA-IR estimates of insulin resistance, and fasting blood glucose but without changes in other circulating lipids, in other liver enzymes or in serum adiponectin [148]. This data led the authors to suggest maintaining vitamin D repletion as an effective strategy for the management of NAFLD [148]. Whatever effect repletion may or may not have on NAFLD itself, this data suggests that vitamin D repletion should reduce the general health risks associated with NAFLD through adequate provision of 25(OH)D to the target tissues, as can be expected in any disorder that reduces serum 25(OH)D concentrations.

Lipid profiles have been reported to be variously affected by vitamin D supplementation over many years. Review and metaanalysis have shown beneficial effects of vitamin D, often in combination with calcium, with consistent improvements in serum triacylglycerides but only minimal improvements, if any, in HDL and LDL cholesterol in most studies [149,150]. Such small effects might reflect lack of benefit or inadequate trial design since a more recent review and metaanalysis suggest more marked benefits. Definitive studies are needed in this area.

#### 10. Importance of early-life vitamin D status for later obesity and subsequent risks of metabolic syndrome, type 2 diabetes mellitus, and cardiovascular disease

Maternal vitamin D metabolism changes during pregnancy [151] (see Chapters 32–34). Although circulating 25(OH)D crosses the placenta poorly [152], there is a marked increase in the activation of 25(OH)D to 1,25(OH)<sub>2</sub>D during early pregnancy within pregnancy

-specific tissues, i.e., the decidua and placenta, and maternal blood  $1,25(\text{OH})_2\text{D}$  concentrations double by the third trimester [153]. At the same time, normal homeostatic downregulation of serum  $1,25(\text{OH})_2\text{D}$  is lost because of epigenetic inactivation of the catabolic enzyme CYP24A1 [154] in conceptual tissue. These changes help to ensure that adequate amounts of  $1,25(\text{OH})_2\text{D}$  are available in the maternal circulation to supply the needs of the developing fetus.

The epigenetic effects of poor maternal nutrition are increasingly well recognized. Maternal vitamin D inadequacy leads to variations in methylation of the promoter region of the calcium transporter gene [155,156], with likely effects on offspring due to changes in the mechanisms relevant to bone health and growth. Furthermore, vitamin D has many other epigenetic effects; thus, early-life vitamin D status can contribute to the determination of later nonskeletal health risks, in ways that cannot be identified by RCTs of supplemental vitamin D later in life. For example, epigenetic effects of experimental maternal vitamin D deficiency persist into adulthood, with long-term effects on the liver and pancreas [58,156,157]. Similarly, children born to vitamin D-deficient mothers were more obese as neonates and aged 1 year as compared with children born to replete women [155–157]. It is generally accepted that many disease risks are transmitted across generations through epigenetic mechanisms. For example, poor intrauterine nutrition, maternal obesity, maternal T2DM, and gestational diabetes (whose prevalence is increased by maternal vitamin D deficiency) are all well-recognized risk factors for increased T2DM risks in human offspring later in life [158–160].

Nutritional “imbalances,” and factors such as paternal smoking and betel chewing, contribute to offspring risks of metabolic syndrome and T2DM, and vitamin D status could affect these risks. Evidence for transgenerational transmission of such effects has been obtained, for example, from human data and from mouse offspring of vitamin D-deficient dams, which showed increased weight, hepatic fatty acid synthase activity, IR, increased pancreatic islet size, and hepatic steatosis [59,161–163].

There are many putative explanations of how early-life vitamin D deficiency could increase offspring obesity risk, including increases in adipogenesis [162] associated with the inhibition of adipocyte maturation into myocytes, aggravated by early obesity-induced increases in adipocyte cell numbers and size that appear to be irreversible, and the induction of permanent changes to hypothalamic appetite regulation [163–165]. Specifically,  $1,25(\text{OH})_2\text{D}$  upregulates the VDR in developing adipocytes, and VDR activation inhibits adipocyte maturation [166], likely favoring their differentiation into myocytes. Seasonal changes in

temperature and solar UVB radiation could also influence these associations; the “winter hypothesis,” suggesting that low winter UVB radiation reduces skin synthesis of vitamin D, signals the need for energy storage, which increases body weight, optimizes heat conservation, and increases tolerance of winter food shortages [167]. However, studies on associations between maternal vitamin D status and offspring fat mass produce inconsistent findings; for example, in two studies in the United Kingdom, one found low-maternal vitamin D status to be associated with greater offspring fat mass at 4 and 6 years of age, while another study from the same geographical area suggested lower offspring fat mass aged 9 years [168,169]. In a societal experiment on the effects of food fortification with vitamin D in Denmark, no differences in body size were seen at 7 years of age between children born before or after implementation of the program [170]. Regardless of the apparent absence of effects of short-term supplemental increases in vitamin D intakes on obesity risks, maternal and early-life vitamin D status could have important influences on later life risks of metabolic abnormalities associated with obesity, including inflammation, dyslipidemia, hypertension, hyperglycemia, overt type 2 diabetes, and cardiovascular disease. Long-term vitamin D repletion may, therefore, provide some protection from the health risks of obesity over the life span. This concept is further supported by the many mechanisms identified as underlying the associations of obesity and the resultant vitamin D deficiency with the health risks, as already discussed, as well as contributing to later ill-health through in utero “programming” of offspring ill health by maternal vitamin D deficiency.

Overall, the various associations between vitamin D insufficiency and obesity-related metabolic abnormalities are very similar in children, adolescents, and adults. Since the development of obesity, its related metabolic abnormalities, and atherosclerotic vascular disease, all begin in childhood and are progressive throughout life, anything that worsens these risks over the life span will increase the risks of these disorders becoming clinically obvious in adults [171,172]. Follow-up of offspring in cohorts where maternal vitamin D status was assessed, in RCTs where maternal vitamin D supplementation has been given, and of populations where vitamin D deficiency has been virtually abolished, as in Finland [173], could eventually clarify the contribution of early-life vitamin D status to later health risks. This is especially important for offspring outcomes that may not be changed by later supplementation or where structural damage has already begun before disease is apparent, as in both T2DM and CVD. Overall, it is plausible that long-term repletion with vitamin D from early in life may have a key role in reducing later health risks.

Childhood obesity is a key determinant of later Mets risks, and the increased health risks in obesity must be aggravated, since the reduced serum 25(OH)D that obesity induces must worsen the provision of 25(OH)D substrate to the tissues for the formation of 1,25(OH)<sub>2</sub>D.

## 11. Obesity, vitamin D, and cancer

Obesity is a well-recognized risk factor for various types of cancer, and it is possible that the reduced circulating 25(OH)D of obesity contributes to these risks [174,175]. How far the increased cancer risks in obesity reflect the effects of the reduced circulating 25(OH)D seen in obesity as discussed before is an important question since lowered circulating 25(OH)D reduces the supply of 25(OH)D to target tissues as a substrate for 1,25(OH)<sub>2</sub>D synthesis and promoting auto- and paracrine functions of vitamin D. Ensuring vitamin D adequacy (by food fortification + targeted supplementation [173]) would be simpler and more cost-effective approach than abolishing the obesity, though overweight/obese people would need higher supplemental intakes than others [75].

## 12. Obesity, COVID-19, and vitamin D

Being overweight or obese is a recognized risk factor for developing severe COVID-19 illness and was associated with increased COVID-19 mortality rates in the recent pandemic. Excess weight is also thought to be a factor leading to the increased severity of this illness in British ethnic minority groups where overweight is a common problem as are deprivation, type 2 diabetes, and vitamin D deficiency [176–178]. COVID-19 often leads to acute pulmonary inflammation, with or without secondary infection, and can develop into the acute respiratory distress syndrome (ARDS), with excessive immune responses (cytokine storm) and high death rates. Such problems increase with inadequate secretion of defensins and cathelicidin, both of which are stimulated by 1,25(OH)<sub>2</sub>D. ARDS worsens with failure to suppress the secretion of proinflammatory cytokines (e.g., IL-6) in combination with reduced production of antiinflammatory cytokines (e.g., IL-10), while 1,25(OH)<sub>2</sub>D has beneficial effects on both those problems [178,179] (see Chapter 99).

Circulating MMPs, mainly MMP2/9, increase in severe, and remain raised in prolonged, COVID-19 illness [180,181]. Targeted MMP2/9 reduction is suggested for treatment of COVID-19 and could potentially also help with long COVID. Vitamin D supplementation reduces abnormally raised circulating MMP2/9 [182]. In ARDS,

pulmonary ACE-2R secretion falls, leading to worsening lung damage. However, vitamin D promotes ACE-2R secretion, specifically in the lungs where ACE-2R has protective effects against ARDS [179]. Overall, therefore, being vitamin D adequate before infection should reduce the risk of illness as has been reported from a large US study where better prepandemic D status was associated dose-wise with reducing infection rates by up to 50% once 25(OH)D values reached ~ 50 ng/mL [~125 nmol/L] [183]. Similar evidence for protection was found in a study from Israel with additional data showing a ×14-fold reduction in the risk of COVID-19 death with previous vitamin D adequacy [184].

In a UK biobank data analysis, obesity, minority ethnicity, and social deprivation were predictors of COVID-19, but adjustment for obesity and ethnicity abolished vitamin D status as a predictor, though those adjustments may be unhelpful since these factors are major determinants of vitamin D deficiency [185–187]. Additionally, though rapidly raising serum 25(OH)D levels have been tested for reduction in COVID-19 risks, benefit has not been reported, even with large doses of vitamin D<sub>3</sub> [188], while benefits have been reported in patients given calcifediol [25(OH)D] in several small studies, including an observational cohort study that suggests a large reduction in mortality [188,189]. This apparent paradox is explained, and is predictable, since rises in serum 25(OH)D with vitamin D treatment are slow (days/week), while serum 25(OH)D rises rapidly with calcifediol treatment (within hours). Furthermore, large bolus doses of D<sub>3</sub> activate autoregulatory mechanisms normally acting to prevent vitamin D toxicity that specifically reduce vitamin D activation [190,191]; those effects persist for at least 3 months, and this form of treatment is known to allow rickets to develop in deficient children (see Chapters 62 and 63). There are, however, no data available from large and adequately designed randomized controlled trials of the use of calcifediol in patients hospitalized with COVID-19, and, until such studies emerge, this form of treatment is unlikely to be accepted for general use.

## 13. Conclusions

A greater volumetric distribution of 25(OH)D appears, at least in part, to be a valid explanation for the lower circulating concentrations of 25(OH)D seen in obesity together with suppression of the hepatic 25-hydroxylation of cholecalciferol that forms 25(OH)D, which also explains the smaller increases in serum 25(OH)D concentrations than expected from studies in normal-weight subjects that are seen with supplementation in obesity. In some, but not all, studies, “free” 25-hydroxyvitamin D concentrations were also lowered in

obesity. Further studies are needed to determine the relative importance of these metabolites in relation to the various health problems associated with obesity in both short and long terms.

Further work is also needed to examine the causality of poor vitamin D status for many more nonskeletal disorders. Similarly, whether the reductions in serum 25(OH)D induced by obesity and diabetes (reverse causality) increase health risks, independently, is an important question since the answer could affect the clinical management of many patients; it could also lead to public health measures for reducing vitamin D inadequacy and hence reduce many health risks prospectively in the many populations where obesity and inadequate vitamin D continue to be common.

Current knowledge on the roles of adequate vitamin D status in the reduction of health risks associated with obesity suggests that maintaining vitamin D adequacy through the life span should significantly reduce the risks of health problems associated with inadequate vitamin D status. However, most RCTs in this area, including those used in metaanalyses, have failed; largely because few subjects with deficiency were recruited into such trials and also because vitamin D dosage was often insufficient to correct deficiency over the duration of the trial. Further high-quality studies that achieve the thresholds reported to be necessary for showing benefits of interest in obesity are still required since the amounts of vitamin D needed to achieve specific target 25(OH)D thresholds in obesity are so much higher in obese than in nonobese subjects. Since the intakes needed to achieve adequate vitamin D status in obesity will also increase with comorbidities such as diabetes and older age, and with the severity of baseline vitamin D deficiency, it will be important to ensure that such trials are correctly designed. Future clinical trials should, for example, define the vitamin D status required for recruitment (a serum 25(OH)D concentration <50 nmol/L) and the vitamin D status that should be achieved (>50 nmol/L), though that target may vary with certain health problems. They should also show that target 25(OH)D concentrations are achieved during trials. While lack of physical activity and unhealthy lifestyle are important risk factors for obesity and for the serious disorders associated with obesity, including the metabolic syndrome, T2DM and CVD, as well as worsening obesity itself, the associated problem of vitamin D deficiency would be much easier to correct (for example, by adequate food fortification plus targeted supplementation) than are lifestyle risk factors such as obesity.

Whatever the value of ensuring vitamin D adequacy may prove to be at the population level, the importance of an effective public health strategy for reducing the risks of metabolic syndrome abnormalities and of CVD

and T2DM is obvious. This strategy should aim to prevent obesity from early in life and include routine normalizing of maternal vitamin D status, since adequate supplies of 1,25(OH)<sub>2</sub>D to the unborn child early in pregnancy reduce later obesity risks. This simple measure would be valuable in supporting other programs aimed at providing all the well-established benefits of weight control.

## 14. Summary points

- Adipose tissue is an important storage site for 25(OH)D, and individuals with obesity are at high risk of low concentrations.
- Weight reduction in the context of obesity is associated with improvements in vitamin D status.
- Obesity affects vitamin D requirement, and while there are different recommendations, intakes that are two to three higher may be required for individuals with obesity compared to normal weight.
- Obesity related vitamin D deficiency may have notable implications for metabolic health, with evidence for increased risks of low-grade inflammation, heart disease, and cancer.

# The role of vitamin D in type 2 diabetes

Anastassios G. Pittas

Tufts Medical Center, Boston, MA, United States

## OBJECTIVES

- Understand the mechanistic pathways that link vitamin D and type 2 diabetes.
- Establish the relationship between low vitamin D status and risk of developing type 2 diabetes and understand limitations of observational studies.
- Evaluate the evidence from clinical trials on the role of vitamin D for the prevention and treatment of type 2 diabetes.
- Synthesize the evidence from the vitamin D and type 2 diabetes prevention trials.
- Recognize the importance of postrandomization biases in trials and the “treat-to-target” concept.
- Discuss the role of adiposity in modulating the effect of vitamin D.
- Examine the safety of vitamin D in people at risk for type 2 diabetes.

## 1. Introduction

Vitamin D has garnered attention for prevention of type 2 diabetes as longitudinal observational studies have shown a consistent association between higher blood 25-hydroxyvitamin D [25(OH)D] levels and lower risk of developing diabetes [1,2]. Potential mechanisms by which vitamin D may affect glucose metabolism include stimulating insulin secretion decreasing systemic inflammation, and improving insulin resistance in muscle and liver [3].

There are three trials that were specifically designed and conducted to test whether vitamin D reduces the rate of progression to diabetes in people with prediabetes [4–6]. This chapter (1) reviews the mechanistic pathways that link vitamin D and type 2 diabetes pathophysiology, (2) describes the consistent association between low vitamin D status and risk of developing type 2 diabetes, (3) synthesize the efficacy-safety evidence from the large vitamin D and type 2 diabetes prevention trials (4) highlights the importance of post-randomization biases in trials and the importance of the “treat-to-target” concept.

## 2. Epidemiology and burden of type 2 diabetes

Diabetes mellitus has become a significant global healthcare problem. According to the United States Centers for Disease Control, about 37.3 million people (about 11.3% of the US population) had diabetes (diagnosed or undiagnosed) in 2019. This total included 37.1 million adults 18 or older, or 14.7% of all US adults. About 8.5 US million adults had diabetes but were not aware that they had it or did not report that they had it [7]. The most common type of diabetes is type 2 diabetes, accounting for over 95% of all diabetes. Type 2 diabetes is often preceded by prediabetes, which is a glycemic state where blood glucose level is higher than normal but not high enough for a diabetes diagnosis. Prediabetes increases a person’s risk of developing type 2 diabetes, heart disease, and stroke. The Centers for Disease Control estimates that 96 million—or more than 1 in 3—US adults aged 18 years or older had prediabetes in 2019. This number includes over 37 million adults aged 45–64 years and over 26 million adults aged 65 years or older. In 2017–20 period, only about 17.4% of people with prediabetes

report that they had ever been notified by a health professional of their prediabetes status; however, this percentage is improved from 6.5% from a decade ago [7]. Diabetes is also an important public health problem worldwide affecting more than 537 million people, and this number is predicted to rise to 643 million by 2030 and 783 million by 2045 [8]. Diabetes is the leading cause of blindness, kidney disease, heart disease, and stroke. In the United States alone, each year up to 25,000 individuals lose their sight, and as many as 28,000 initiate treatments for chronic kidney failure because of diabetes. People with diabetes are four times more likely to develop cardiovascular disease (coronary artery disease, peripheral vascular disease, or stroke) compared with those without diabetes. Beyond its devastating human toll, diabetes is also associated with increasing costs, estimated at more than 300 billion in the United States alone and more than half a trillion dollars worldwide [9].

Although therapies for type 2 diabetes and its complications have improved over the past few decades, the increasing burden of type 2 diabetes highlights the need for innovative approaches for the management and prevention of the disease. Epidemiologic data suggest that 9 out of 10 cases of type 2 diabetes could be attributed to modifiable habits and lifestyle [10]. In clinical trials, lifestyle changes aiming at weight loss are successful at reducing risk of type 2 diabetes [11]. However, long-term weight maintenance in the clinical setting has proved elusive with lifestyle changes alone. Moreover, even after successful weight loss, there is still significant residual risk (~40–50%). Therefore, identification of weight-independent and easily modifiable risk factors is urgently needed to prevent type 2 diabetes and decrease patient and societal burden.

Based on accumulating evidence from animal and human studies (observational studies and clinical trials), as reviewed in this chapter, suboptimal vitamin D status has emerged as a risk factor for type 2 diabetes and vitamin D has been proposed as an intervention when caring for patients at risk for type 2 diabetes.

### 3. Biologic plausibility of the link between vitamin D and type 2 diabetes

For glucose intolerance and type 2 diabetes to develop, impaired pancreatic beta-cell function, insulin resistance, and systemic inflammation are often present [12,13]. There is evidence that vitamin D modulates many of these mechanisms, as described next.

#### 3.1 Vitamin D and pancreatic beta-cell function

There are several lines of evidence supporting a beneficial role for vitamin D in pancreatic beta-cell function

(Fig. 76.1) [14–16]. In *in vitro* and *in vivo* studies, vitamin D deficiency impairs glucose-mediated insulin secretion from rat pancreatic beta-cells [17–21], while vitamin D supplementation restores glucose-stimulated insulin synthesis and secretion [17,20–24]. Vitamin D may have a direct effect on beta-cell function mediated by binding of the circulating active form, 1,25(OH)<sub>2</sub>D, to the vitamin D receptor (VDR), which is expressed in pancreatic beta-cells [25,26]. Furthermore, mice lacking a functional VDR show impaired insulin secretory response following a glucose load, attributed to a decrease in insulin synthesis due to a reduction in insulin stored in the beta-cell [27]. In addition, transgenic mice overexpressing VDR in beta-cells were protected against streptozotocin-induced diabetes and had preserved beta-cell mass and a reduction in islet inflammation [28]. Activation of vitamin D also occurs within the pancreatic beta-cell by the 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase enzyme (CYP27B1), which is expressed in pancreatic beta-cells [29]. Such mechanism allows for an important paracrine effect of circulating 25[OH]D. An indirect effect of vitamin D on the pancreatic beta-cell may be mediated via its regulation of extracellular calcium concentration and calcium flux through the beta-cell [30]. Insulin secretion is a calcium-dependent process [31]; therefore, alterations in calcium flux can have an effect on insulin secretion [32–35]. Vitamin D also regulates calbindin, a cytosolic calcium-binding protein found in many tissues including beta-cells [25,36]. Calbindin is a modulator of depolarization-stimulated insulin release via regulation of intracellular calcium [37]. Another potential pathway is through the pancreatic islet renin–angiotensin system (RAS), which appears to play a role in maintaining islet cell mass and insulin secretion [38]. VDR-knockout (KO) mice have increased islet RAS expression compared with wild-type (WT) mice, and 1,25(OH)<sub>2</sub>D prevents and corrects induction of RAS component production under high-glucose conditions with concomitant increases in islet insulin secretion [39]. Finally, vitamin D may promote beta-cell survival by modulating the generation (e.g., through inactivation of nuclear factor- $\kappa$ B [NF- $\kappa$ B]) and effects of cytokines [40,41]. In cross-sectional human studies, an association between blood 25(OH)D level and insulin secretion has been reported in some [42–46] but not all studies [47]. Trials that have reported on the effect of vitamin D supplementation on beta-cell function have been inconclusive [48–51]. The divergent results may be due to differences in populations studied (normal glucose tolerance, prediabetes, or established diabetes), methods of measuring insulin secretion, and beta-cell function and/or variation in the dose and duration of treatment with vitamin D (e.g., intermittent, very high doses of vitamin D are considered nonphysiologic

**FIGURE 76.1 Vitamin D and pancreatic beta cell function.** Vitamin D can promote pancreatic beta cell function in many ways. The active form of vitamin D,  $1,25(\text{OH})_2\text{D}$ , enters the beta cell from the circulation and interacts with the vitamin D receptor-retinoic acid x-receptor complex (VDR-RXR) to enhance the transcriptional activation of the insulin gene and increase the synthesis of insulin. Vitamin D may promote beta-cell survival by modulating the generation (through inactivation of nuclear factor kappa B [NF- $\kappa$ B]) and effects of cytokines. The anti-apoptotic effect of vitamin D may also be mediated by downregulating the Fas-related pathways (Fas/Fas-L). Activation of vitamin D also occurs intracellularly by 25-hydroxyvitamin D- $1\alpha$ -hydroxylase enzyme (CYP27B1), which is expressed in pancreatic beta cells. Vitamin D may also have effects on the expression of cytoskeletal and intracellular trafficking genes along with genes involved in ion transport to influence **insulin exocytosis**. The effects of vitamin D may be mediated indirectly via extracellular calcium ( $\text{Ca}^{2+}$ ), calcium flux through the beta cell and intracellular calcium ( $\text{Ca}^{2+}$ )<sub>i</sub>. Alterations in calcium flux can directly influence insulin secretion, which is a calcium-dependent process. Vitamin D also regulates calbindin, a cytosolic calcium-binding protein found in beta cells, which acts as a modulator of depolarization-stimulated insulin release via regulation of intracellular calcium. Calbindin may also protect against apoptotic cell death via its ability to buffer intracellular calcium. Vitamin D may also correct induction of RAS component production under high-glucose conditions with concomitant increases in islet insulin secretion.

compared with daily doses). In the D2d study, discussed in detail later, vitamin D<sub>3</sub> at 4000 IU/day did not change an OGTT-derived index of beta-cell function in people with prediabetes not selected for vitamin D status; however, there was significant improvement in beta-cell function among those with blood  $25(\text{OH})\text{D}$  below 12 ng/mL [52].

### 3.2 Vitamin D and insulin sensitivity

In peripheral insulin-target cells, active vitamin D metabolites may enhance insulin sensitivity in several ways, as indicated by the presence of the vitamin D receptor in skeletal muscle and adipose tissue (Fig. 76.2) [15,53–57].  $1,25(\text{OH})_2\text{D}$  appears to directly augment insulin sensitivity by stimulating the expression of insulin receptors [58–61];  $1,25(\text{OH})_2\text{D}$  enters insulin-responsive cells and interacts with the VDR, activating the VDR-retinoic acid X-receptor (RXR) complex, which, in turn, binds to a vitamin D response element

found in the human insulin receptor gene promoter. The result is enhanced transcriptional activation of the insulin receptor gene, which increases the total insulin receptors without altering receptor affinity.  $1,25(\text{OH})_2\text{D}$  may also enhance insulin sensitivity by transcriptionally activating peroxisome proliferator-activated receptor delta, a transcription factor implicated in the regulation of fatty acid metabolism in skeletal muscle and adipose tissue [62]. An indirect effect of  $1,25(\text{OH})_2\text{D}$  on insulin sensitivity might also be exerted via its important and well-recognized role in regulating extracellular calcium level and flux through cell membranes. Calcium is known to be essential for insulin-mediated intracellular processes in insulin-responsive tissues such as skeletal muscle and adipose tissue [63,64], with a very narrow range of intracellular calcium needed for optimal insulin-mediated functions [65]. Changes in intracellular calcium in insulin target tissues may contribute to peripheral insulin resistance [65–71] via impaired insulin signal transduction [71,72], leading to decreased glucose transporter

**FIGURE 76.2 Vitamin D and insulin action.** In peripheral insulin-target cells, vitamin D may directly enhance insulin sensitivity in several ways. The active form of vitamin D,  $1,25(\text{OH})_2\text{D}$ , enters the insulin-responsive cells from the circulation and interacts with the vitamin D receptor-retinoic acid x-receptor complex (**RXR-VDR**). The complex binds to a vitamin D response element (**VDRE**), which is found in the human insulin receptor gene promoter, to enhance the transcriptional activation of the insulin receptor gene and increase the synthesis of insulin receptors (**INS-R**) which act to promote glucose uptake via the glucose transporter 4 (**GLUT-4**) receptor and/or by activating peroxisome proliferator-activated receptor delta (**PPAR-δ**), a transcription factor implicated in the regulation of fatty acid metabolism in skeletal muscle and adipose tissue. The effects of vitamin D may be mediated indirectly via regulating extracellular calcium ( $\text{Ca}^{2+}$ ), calcium flux through the cell and intracellular calcium ( $[\text{Ca}^{2+}]_i$ ). Vitamin D may promote beta-cell survival by modulating the generation (through downregulation of nuclear factor- $\kappa\text{B}$  and effects of cytokines). Vitamin D may also affect insulin resistance indirectly through the renin-angiotensin system (**RAS**) via the angiotensin 1 receptor (**AT1R**).

activity [71–73]. Hypovitaminosis D also leads to increased parathyroid hormone (PTH) concentration, which has been associated with increased insulin resistance [74,75]. Vitamin D may also affect insulin resistance indirectly through RAS, as described in the next section. Finally, vitamin D insufficiency is associated with increased fat infiltration in skeletal muscle, independent of body mass, which may further contribute to decreased insulin action [76]. In observational human studies, low vitamin D status (assessed by self-reported vitamin D intake or blood  $25(\text{OH})\text{D}$  level) has been associated with simple indices of insulin resistance, including measurements of fasting insulin and homeostasis model assessment (HOMA-IR) [43–46,77–85], but the association is not consistent [47,81,86,87]. A recent metaanalysis reported no effect of vitamin D supplementation on insulin sensitivity in adults with or at increased risk for insulin resistance [88]; however, this metaanalysis had major limitations, primarily based on the low-quality, short-term follow-up, and heterogeneity of the included studies, including in the definitions of insulin resistance [89].

### 3.3 Vitamin D and systemic inflammation

Systemic inflammation, via an increase in proinflammatory cytokines, plays an important role in the pathogenesis of type 2 diabetes, mostly by promoting insulin resistance; pancreatic beta-cell function may also be affected via cytokine-induced apoptosis [90–92]. Vitamin D can lessen the effects of systemic inflammation on type 2 diabetes risk by altering the balance between pro- and anti-inflammatory cytokines, [93,94].  $1,25(\text{OH})_2\text{D}$  may improve insulin sensitivity and protect against beta-cell cytokine-induced apoptosis by directly modulating the expression and activity of cytokines [41,95–97]. One such pathway may be through downregulation of NF- $\kappa\text{B}$ , which is a major transcription factor for TNF- $\alpha$  and other inflammatory mediators [98,99]. Another pathway that may, at least in part, mediate the antiapoptotic effect of  $1,25(\text{OH})_2\text{D}$  on beta-cells is through counteracting cytokine-induced Fas expression [100]. Several other immune-modulating effects of  $1,25(\text{OH})_2\text{D}$  (e.g., blockade of dendritic cell differentiation, inhibition of lymphocyte proliferation, inhibition of foam cell

formation and cholesterol uptake in macrophages, enhanced regulatory T lymphocyte development) [96,101] may provide additional pathways of protection against inflammation-induced type 2 diabetes risk. Low blood 25(OH)D concentration has been associated with elevated concentration of markers of systemic inflammation in some [84,102–104] but not all human studies [77,105–109].

### 3.4 Other mechanisms

Beyond effects on pancreatic beta-cell function, insulin action, and systemic inflammation, there are other mechanisms of how vitamin D may modulate risk of type 2 diabetes.

It is well established that overweight and obesity are risk factors for vitamin D deficiency typically attributed to a “sequestration” effect of vitamin D in adipose tissue or simply a “volumetric dilutional” effect, due to suboptimal intake, or reduced biosynthesis from limited sunlight exposure [110–112]. Recent evidence shows that obesity represses vitamin D bioactivation by CYP2R1, leading to reduced production of 25(OH)D, while weight loss upregulates CYP2R1 expression [113,114]. These results suggest that the effect of vitamin D on diabetes risk may be mediated via its conversion to 25(OH)D by CYP2R1, which is primarily expressed in the liver [115] and subsequently to 1.25(OH)<sub>2</sub>D by CYP27B1 in the kidney and pancreatic endocrine cells. Therefore, people with obesity are at risk for type 2 diabetes, at least in part, due to their inability to optimize vitamin D activation pathways and their glucose tolerance would be affected the most by vitamin D deficiency.

Other pathways may be relevant. For example, the central nervous system can directly control hepatic glucose production, insulin secretion, and glucose handling by the muscle and kidney [116]. Specifically, the paraventricular nucleus (PVN) is a key hypothalamic area that integrates signals from a variety of brain regions and has important regulatory functions for hepatic glucose control. The PVN may also alter peripheral glucose levels by modifying pancreatic function [116]. Vitamin D is well known to be integral to normal brain development [117], and there is data to support that vitamin D action in the brain is an essential pathway to halt glucose intolerance in diet-induced obese animals [118]. These centrally mediated effects of vitamin D on glucose homeostasis may be mediated by improving insulin action within the hypothalamus or through antiinflammatory actions in the hypothalamus [119,120].

## 4. Observational studies on vitamin D and type 2 diabetes

### 4.1 Seasonal and geographic studies

An association between vitamin D status and type 2 diabetes is suggested by a reported seasonal variation in glycemic control in patients with type 2 diabetes, being worse in the winter [121,122] when hypovitaminosis D is highly prevalent due to decreased exposure to solar UVB light. A strong geographic variability has been described in relation to type 1 diabetes, with incidence rates approaching zero in regions with high UVB irradiance [123–125]; however, a similar geographic association between decreasing UVB exposure and prevalent type 2 diabetes is not seen. Although moderate-level evidence suggests that recreational sun exposure is inversely associated with risk of type 2 diabetes, obesity and lifestyle (diet, exercise), which align with sun exposure, are confounders [126] in the reported relationship.

### 4.2 Case–control and cross-sectional studies

The initial evidence for a role of vitamin D in type 2 diabetes comes from case–control studies, the first of which was published in 1979 [127]. These studies have included small numbers of participants, and most [81,128–138], but not all [81,127,134,139], have reported that patients with type 2 diabetes or glucose intolerance have lower blood 25(OH)D concentration compared with controls without diabetes.

Several large cross-sectional studies have examined the association between vitamin D status (assessed by blood 25(OH)D concentration or self-reported vitamin D intake) and prevalence of glucose intolerance or type 2 diabetes or metabolic syndrome. The latter describes the clustering of several cardiometabolic risk factors (abdominal obesity, hypertension, dyslipidemia defined as high triglycerides and low HDL cholesterol, and hyperglycemia), and it is closely linked to type 2 diabetes [140]. Most studies have reported inverse associations between vitamin D status and glucose intolerance and type 2 diabetes [45,75,78,82,132,141–149], metabolic syndrome [45,83,143,147,149–152], or markers of insulin resistance [46,82], while others did not show any associations [45,75,78,106,142,153–160].

In a large cross-sectional study with data from the US-based National Health Nutrition Examination Survey (NHANES), blood 25(OH)D concentration was inversely associated with prevalence of diabetes in a dose-dependent pattern in non-Hispanic White people and Mexican-American people, after multivariate adjustment, including BMI [78]. In this study, there

was no association in non-Hispanic Black people despite lower 25(OH)D concentration found in this racial group, which may be explained by the observation that people with darker skin complexity exhibit a different vitamin D, calcium, and PTH homeostasis compared with people with lighter skin complexity [161]. A subsequent analysis from NHANES did not find an interaction between blood 25(OH)D concentration and race/ethnicity on glycemic outcomes [82]. Additional studies using NHANES data have repeatedly confirmed the inverse association between blood 25(OH)D concentration and glycemia [82,143,144,146,147], which has also been reported in other large cohorts from the United States [75,149,162], Europe [141,151,152], and China [83].

Vitamin D status has also been inversely associated with the prevalence of the metabolic syndrome in some [45,80,81,83,143,149–152,154,157] but not all studies [75,81,155,163]. In the NHANES database, serum 25(OH)D concentration (after multivariate adjustment) was inversely associated with prevalent metabolic syndrome among both genders and all three major racial or ethnic groups [143,157]. A similar inverse association has also been reported in two cohorts from the United Kingdom [80,151], in a cohort from the Netherlands [152], and in a cohort from China [83]. The clinical components of the metabolic syndrome that have consistently been independently associated with low blood 25(OH)D concentration are abdominal obesity and hyperglycemia [83,152]; therefore, the association between 25(OH)D status and metabolic syndrome reported in these cross-sectional studies may simply reflect the well-established inverse association between 25(OH)D status and adiposity [78,164–166].

### 4.3 Longitudinal cohort studies

Cross-sectional studies cannot establish the direction of causality between vitamin D status and risk of type 2 diabetes; therefore, longitudinal observational studies where vitamin D status is assessed prior to the development of the outcome of interest (incident type 2 diabetes) are methodologically preferred. In most longitudinal observational studies, a significant association between high blood 25(OH)D concentration and lower incidence of type 2 diabetes has been reported [1,154,167–182]; but no association was observed in other studies (Table 76.1) [181,183–188]. These longitudinal studies included participants (nearly all of White race) who were followed from 1.3 to 22 years for incident type 2 diabetes. Six studies included postmenopausal women only [154,167,170,183,184,188]. Studies have assessed vitamin D status by self-reported total vitamin D intake [154,167], predicted 25(OH)D score [169], or by blood 25(OH)D concentration [1,168,170–188]

(Table 76.1A). Ascertainment of type 2 diabetes was by validated self-report [1,154,167,170,186], by laboratory measurement [177–181,186], by combination of self-report and laboratory measurement or validation by participant's physician [169,172,174–176,182–185], by clinical diagnosis [173], or by hospital/national registry-based data [168,171,181].

In the Nurses' Health Study, after multivariate adjustment for age, BMI, and nondietary covariates, women who reported consumption of more than 800 IU/day of vitamin D had a 23% lower risk for developing incident type 2 diabetes compared with women who reported consumption of less than 200 IU/day [167]. The association, however, was attenuated and became non-statistically significant after adjusting for dietary factors. The dietary variables solely responsible for attenuation of the results were magnesium and calcium, which share dietary sources with vitamin D. In the same study, women who reported the highest calcium (>1200 mg/day) and vitamin D (>800 IU/day) intake (1.3% of the cohort) had 33% lower risk of type 2 diabetes compared with women with the lowest calcium (<600 mg/day) and vitamin D (<400 IU/day) intakes, which highlights a potentially important role for calcium intake in type 2 diabetes risk. In the Framingham Offspring Study (men and women), investigators used a subsample of the cohort to develop a regression model to predict blood 25(OH)D concentrations from age, sex, body mass index, month of blood sampling, total vitamin D intake, smoking status, and total energy intake [169]. Using this model, a predicted 25(OH)D score was calculated for each nondiabetic participant, and the association between the predicted 25(OH)D score and incidence of type 2 diabetes was assessed during a mean follow-up period of 6 years. Compared with participants in the lowest tertile of the predicted 25(OH)D score, those in the highest tertile had 40% lower incidence of type 2 diabetes after multivariate adjustment.

Several case–control studies nested within larger cohorts have reported the association between blood 25(OH)D concentration and incident type 2 diabetes [168,170,176,180,181,184] (Table 76.1). In these studies, blood samples from cases (i.e., participants who develop type 2 diabetes) and matched controls (i.e., participants who did not develop diabetes during the follow-up period) are retrieved from stored samples, and blood 25(OH)D is measured at a time when all participants were free of type 2 diabetes. Analyses then compare the 25(OH)D concentration between cases and controls. The study by Knekt et al. which pooled data from two cohorts in Finland (total of 7503 participants), included 412 cases and 986 matched controls [168]. After multivariate adjustment including BMI, participants who were in the highest quartile of 25(OH)D at baseline (mean 25[OH]D 27.6 ng/mL) compared with those in

<sup>a</sup>Number of cases if nested case–control study.

<sup>b</sup>Highest/lowest risk category versus reference category.

<sup>c</sup>Study quality is determined based on a three-category grading system. Good quality studies adhere most closely to the commonly held concepts of high quality including clear descriptions of the population and setting; unbiased assessments of vitamin D status and outcomes; appropriate statistical analysis including multivariable analysis adjusting for age, race, weight, and sun exposure and intention-to-treat analysis; no obvious reporting omissions or errors; and  $<20\%$  dropouts. Fair quality studies have some deficiencies in the above criteria, but these are unlikely to cause major bias. Studies that used vitamin D intake or predicted 25(OH)D score as the predictor are rated fair. Poor quality studies have major deficiencies in design, analyses, or reporting, such that major bias could not be excluded.

To convert 25(OH)D concentration from ng/mL to nmol/L multiply by 2.459.

the lowest quartile (mean 25[OH]D 8.9 ng/mL) had 40% lower risk of developing type 2 diabetes. The result was entirely driven by a lower risk among men only while there was no significant association among women. Another nested case–control study by Pittas et al. was conducted in the Nurses' Health Study among 608 women with newly diagnosed type 2 diabetes and 559 matched controls [170]. After adjusting for matching factors and diabetes risk factors, including BMI, the odds ratio for incident type 2 diabetes in the top (median 25 [OH]D 33.4 ng/mL) versus the bottom (median 25 [OH]D 14.4 ng/mL) quartile of 25(OH)D was 0.52 (95% confidence interval, 0.33, 0.83). The association was consistent across subgroups of baseline BMI, age, and calcium intake although the association appeared to be stronger among overweight/obese versus normal-weight women. In the same study, spline regression models showed no apparent threshold and no deviation from linearity for the relation between 25(OH)D and risk of incident type 2 diabetes, although the shape of the figure suggested a stronger decrease in risk within the higher range of plasma 25(OH)D concentration, above 30–35 ng/mL (Fig. 76.3). Three more nested case–control studies from Germany [176], Sweden [180], and the United Kingdom [181] also showed strong inverse associations between high levels of blood 25(OH)D and incident type 2 diabetes. A post-hoc analysis of three nested case-control studies of fractures, colon cancer, and breast cancer that measured blood 25(OH)D at baseline in women participating in the

WHI study reported no association among older postmenopausal women [184].

In addition to the nested case–control studies, several longitudinal cohort studies have been published, and nearly all of them have reported inverse associations between blood 25(OH)D concentration and incident type 2 diabetes (Table 76.1). Several metaanalyses have summarized results from the observational studies. In a study by Song et al. which combined data from a total of 21 longitudinal observational studies (76,220 participants and 4996 incident type 2 diabetes cases), there was a significant favorable association between 25(OH)D concentration and incident type 2 diabetes (risk ratio 0.62; 95% confidence interval [CI] 0.54–0.70 for the highest vs. lowest 25[OH]D concentration) [189]. A spline regression model showed that higher 25(OH)D levels were monotonically associated with a lower diabetes risk. This inverse association did not differ by sex, duration of follow-up, study sample size, diabetes diagnostic criteria, or 25(OH)D assay method. In another metaanalysis that included data from 22 longitudinal studies (8492 cases and 89,698 noncases), one standard deviation (10 mg/dL) lower 25(OH)D concentration was associated with an increased risk of type 2 diabetes with moderate evidence of heterogeneity [190]. In a more recent metaanalysis that combined data from 28 longitudinal studies, there was a 34% lower risk of type 2 diabetes (risk ratio 0.66; 95% confidence interval) when comparing individuals with the highest category of 25(OH)D with those in the lowest [191]. In the latest metaanalysis of large longitudinal observational studies, a 1–standard deviation higher level of total 25(OH)D was associated with 20% lower risk of type 2 diabetes [192].

Nearly all observational cohort studies have examined the association between a single 25(OH)D measurement at baseline and risk of developing type 2 diabetes; however, a single 25(OH)D measurement may not reflect long-term vitamin D status during follow-up. A longitudinal observational study by Pittas et al. examined the association between blood 25(OH)D level, measured annually, and risk of incident type 2 diabetes among participants with prediabetes who were randomized to the intensive lifestyle or placebo arms of the Diabetes Prevention Program [193]. By measuring 25(OH)D at multiple time points, this study obtained an integrated measure of intratrial vitamin D status for each participant, rather than relying on a single baseline value, as all other observational studies have done. After multivariate adjustment, including for the Diabetes Prevention Program lifestyle intervention, there was an inverse association between intra-study blood 25(OH)D level and incident type 2 diabetes. The hazard ratio for diabetes in the top tertile of blood 25(OH)D (mean 30 ng/mL) versus the bottom tertile (mean 13 ng/mL)

**FIGURE 76.3** In the Nurses' Health Study (healthy women at average risk for diabetes), there was a progressively lower risk of developing type 2 diabetes with increasing concentration of blood 25(OH)D without an apparent plateau.

**FIGURE 76.4** Dose–response relationship between blood 25(OH)D concentrations and the relative risk for type 2 diabetes mellitus. Results of restricted cubic splines analysis of relative risks standardized to a common reference category with 12 ng/mL 25(OH)D as midpoint and inverse variance weights. Dashed lines indicate 95% confidence. From Figure 6 in Ref. [191].

was 0.72 (95% confidence interval 0.56–0.90). As in the analysis in the Nurses’ Health Study, there was no apparent threshold for the relation between 25(OH)D level and incident diabetes, and results suggested a stronger decrease in diabetes risk for 25(OH)D levels above >50 ng/mL although very few participants achieved that level.

Findings in the Nurses’ Health Study and Diabetes Prevention Program cohorts are fully concordant with those from other observational longitudinal studies that have reported on the association between higher blood 25(OH)D and lower risk of developing type 2 diabetes. When combining such data in a metaanalysis, results mirrored those from the Nurses’ Health Study and Diabetes Prevention Program cohorts: higher 25(OH)D levels (>40 ng/mL) conferred lower risk of developing diabetes, with no apparent plateau for benefit up to concentrations of about 65 ng/mL (Fig. 76.4) [189,191].

#### 4.4 Mendelian randomization studies

Observational studies using Mendelian randomization approaches have shown mixed results with most of them reporting no associations between genetically predicted blood 25(OH)D concentration and new-onset type 2 diabetes [187,190,194–196], while others reporting inverse associations between higher 25(OH)D levels and new-onset type 2 diabetes [197–199]. The theoretical advantage of the Mendelian randomization studies, which examine the association between genetic variants (single-nucleotide polymorphism) that influence blood 25(OH)D concentration and risk of type 2 diabetes, is

that the measured association with the outcome of interest is less likely to be affected by confounding or reverse causation, which are common challenges in conventional observational studies. However, Mendelian randomization studies center upon assumptions that are not relevant to vitamin D physiology [190]. For example, the alleles included in genetically predicted 25(OH)D level account for less than 5% of the variance on blood 25(OH)D level, which is not surprising given that 25(OH)D concentration is primarily a function of exposure to UVB light and to a lesser degree, dietary intake and supplementation. In general, these studies have examined genetic variants shown to be associated with 25(OH)D concentration and implicated in the synthesis, transport, and metabolism of vitamin D: DHCR (encoding 7-dehydrocholesterol reductase enzyme for synthesis of previtamin D<sub>3</sub>), CYP2R1 (encoding the 25-hydroxylase enzyme for conversion of vitamin D<sub>3</sub> to 25[OH]D), GC (the group-specific component that encodes vitamin D-binding protein), and CYP24A1 (encoding the 24-hydroxylase involved in the clearance of 25[OH]D). One potential limitation is that many of these gene variants have pleiotropic effects beyond determining 25(OH)D concentration. In studies that used the two “synthesis” variants that are specific to 25(OH)D and do not have pleiotropic effects, higher genetically determined 25(OH)D levels were associated with reduced risk of type 2 diabetes [198,199]. In one study among Chinese participants, a 10 ng/mL higher genetically determined 25(OH)D concentration based on “synthesis” variants only was associated with a 14% lower risk of diabetes [198]. In another study among individuals of European ancestry, for 1-standard deviation increment of

genetically determined 25(OH)D concentration, there was a 10% lower risk of developing type 2 diabetes based on three variants within or near genes involved in vitamin D synthesis [199]. Furthermore, Mendelian randomization studies cannot predict amounts of bioavailable vitamin D and cannot distinguish between endogenous and exogenous vitamin D. Indeed, variation in the DHCR7 gene, which is related to endogenous production of vitamin D, has been associated with type 2 diabetes risk [197]. There is also little correlation between 25(OH)D (the predictor in Mendelian randomization studies) and the active form of vitamin D ( $1,25[\text{OH}]_2\text{D}$ ). Another limitation of Mendelian randomization studies is that they are limited to participants of European origin, which limits transferability of findings to other racial and ethnic groups. Another explanation why Mendelian randomization studies have not reported consistent associations between genetically predicted 25(OH)D concentration and type 2 diabetes is because they have assumed linear dose–response relationships. Conventional observational analyses have reported nonlinear associations between measured blood 25(OH)D level and new-onset diabetes with the highest risk being among those with the lowest 25(OH)D levels; therefore, standard Mendelian randomization methods that assume linearity provide an incomplete picture of physiology. Promising new approaches in Mendelian randomization analyses allow for the study of nonlinear associations between the exposure and outcome. For example, in two recent publications that did stratified Mendelian randomization analyses in population subgroups with different 25(OH)D concentrations, inverse causal relationships were uncovered between genetically predicted 25(OH)D and all-cause mortality [200] and cardiovascular disease [201]. However, the methods applied by the investigators in this analysis have been questioned. In summary, results from Mendelian randomization studies should be interpreted cautiously because they may lead to unwarranted conclusions of no association with type 2 diabetes [190].

#### 4.5 Limitations of observational studies and the issue of confounding

Overall, the evidence from the mechanistic studies and human observational and ecologic studies suggests an association between low vitamin D status and risk of type 2 diabetes. However, definite conclusions cannot be drawn solely based on this evidence for a variety of reasons: (1) Ecologic studies provide interesting data and assist in generating hypotheses; however, they are likely to be confounded by many variables. For example, worsening glycemic control in the winter may be due to physical inactivity and weight gain, which are common in the winter months. (2) In cross-sectional or case–control

studies, vitamin D was measured in patients with glucose intolerance or established diabetes; therefore, these measures may not reflect vitamin D status prior to diagnosis and, as a result, the causative nature of the reported associations cannot be established. (3) There is considerable variability among the various cohorts (normal glucose tolerance versus diabetes [newly diagnosed vs. established], age, ethnicity, latitude, mean vitamin D status, etc.), which makes it difficult to compare, contrast, and combine results. (4) In many observational studies, there is lack of adjustment for important confounders.

The most important limitation of the observational studies is residual confounding, which may explain, at least in part, the inverse association between vitamin D status and risk of type 2 diabetes reported in nearly all observational studies. Vitamin D status is an excellent marker of good health, as high 25(OH)D concentration is associated with young age, normal body weight, and a healthy lifestyle, including good dietary and exercise behaviors. A lower vitamin D status may reflect chronic nonspecific illness, which may prevent individuals from engaging in outdoor activities and sun exposure. Vitamin D is also associated with smoking, parental history of cardiovascular disease, and less alcohol intake [202], which are all risk factors for type 2 diabetes. Additional issues related to food synergy may further complicate the study of the association between vitamin D and type 2 diabetes [203]. For example, a higher vitamin D intake is often associated with higher intake of a certain food groups (e.g., dairy) or an overall “prudent” dietary pattern; therefore, additional components in foods that are consumed with vitamin D may have direct effects on type 2 diabetes or, alternatively, foods rich in vitamin D may replace other foods that increase risk of these conditions. Mendelian randomization studies have attempted to address confounding; however, as noted earlier, Mendelian randomization studies involve many assumptions that may not be relevant in the study of vitamin D and type 2 diabetes risk.

### 5. Vitamin D supplementation in people with normal glucose tolerance or type 2 diabetes

Several trials have reported the effect of vitamin D (ergocalciferol [ $\text{D}_2$ ] or cholecalciferol [ $\text{D}_3$ ] or eldcalcitol [an analog of calcitriol, the active form of vitamin  $\text{D}_3$ ]) supplementation (with or without calcium) on various outcomes related to diabetes, including changes in glycemic measures, insulin sensitivity, beta-cell function, development of diabetes, or regression to normal glucose regulation from prediabetes (Table 76.2). Trials have included participants with normal glucose tolerance, at risk for diabetes, prediabetes (based on glycemic measures), or established type 2 diabetes (early stage or

**TABLE 76.2** Randomized controlled trials of the effect of vitamin D (with or without calcium) on glucose tolerance in adults with normal glucose tolerance or established type 2 diabetes.—cont'd

First author year of publication (country)	Mean baseline age (range), y	Target population	Baseline 25(OH)D, ng/mL	Interventions (number of participants)	Study duration	Effect of vitamin D versus placebo/control	Study quality
Kampmann (2014) (Denmark)	60	Type 2 diabetes; and 25(OH)D < 20 ng/mL	13	D <sub>3</sub> 11,200 IU/day for 2 weeks, then D <sub>3</sub> 5,600 IU/day for 10 weeks (n = 8) versus placebo (n = 7)	12 weeks	↔ HbA1c ↔ Insulin sensitivity	Fair
Al-Sofiani (2015) (Saudi Arabia)	55 (21–75)	Type 2 diabetes and 25(OH)D < 20 ng/mL	13	D <sub>3</sub> 5,000 IU/day (n = 10) versus placebo (n = 10)	12 weeks	↔ HbA1c ↑ HOMA%B ↔ HOMA-IR	Poor
Krul-Poel (2015) (Netherlands)	67 ± 8	Type 2 diabetes	24	D <sub>3</sub> 50,000 IU/month (~1,666 IU/day) (n = 129) versus placebo (n = 132)	24 weeks	↔ HbA1c ↔ FG ↔ HOMA-IR and HOMA-B	Fair
Anayanwu (2016) (Nigeria)	35–65	Type 2 diabetes, non-insulin requiring with poor glycemic control and “vitamin D deficiency”	NA	D <sub>3</sub> 3,000 IU/day (n = 21) versus placebo (n = 21)	12 weeks	↓ HbA1c ↓ FG	Poor
Gulseth (2017)	56	Type 2 diabetes and 25(OH)D < 20 ng/mL	15	D <sub>3</sub> 400,000 IU once plus 200,000 IU once if needed to keep 25(OH)D > 40 ng/mL (n = 33) versus placebo (n = 29)	6 months	↔ HbA1c ↔ FG ↔ Fasting insulin/C-peptide ↔ AIR ↔ Glucose infusion rate	Fair
Upreti (2018) (India)	49	Type 2 diabetes and hypovitaminosis D	25	D 60,000 IU/week × 6, then monthly (n = 34) versus placebo (n = 37)		↓ HbA1c ↓ FG ↓ 2 hG	Poor
Khan (2018) (India)	40–70	Type 2 diabetes on metformin and 25(OH)D < 20 ng/mL	13	D <sub>3</sub> 50,000 IU/week (n = 70) versus placebo (n = 70)	12 weeks	↓ HbA1c [ <i>P</i> < .01]	Poor
Angellotti (2019) (US)	60	Stable type 2 diabetes (lifestyle or metformin)	27	D <sub>3</sub> 4,000 IU/day (n = 66) versus placebo (n = 61)	48 weeks	↔ Insulin secretion rate ↔ HbA1c ↔ FG ↔ 2 hG	Good

Lemieux (2019) (Canada)	40–70	High risk for type 2 diabetes or newly diagnosed type 2 diabetes on metformin and 25(OH)D < 20 ng/mL	20	D <sub>3</sub> 5,000 IU/day to reach 25(OH)D > 30 ng/mL (n = 48) versus placebo (n = 48)	6 months	↑ Peripheral insulin sensitivity (clamp) ↑ DI ↔ HbA1c ↔ FG ↔ 2 hG	Good
El Hajj (2020) (Lebanon)	66	Type 2 diabetes and 25(OH)D < 20 ng/mL	14	D <sub>3</sub> 10,000 IU 3 times a week (n = 48) versus placebo (n = 49)	6 months	↔ HbA1c ↔ FG	Fair
Cojic (2021) (Serbia)	50	Stable type 2 diabetes on metformin and 25(OH)D < 20 ng/mL	20 ng/mL	D <sub>3</sub> 50,000 IU/week for 3 months, then 14,000 IU/week for 3 months (n = 65) versus placebo (n = 65)	6 months	↓ HbA1c ↓ FG	Poor

↑, statistically significant increase (improvement vs. comparison group); ↓, statistically significant decrease (improvement vs. comparison group); ↔, no statistically significant change; 2 hG, glucose 2 h after a 75 g oral glucose load; 25(OH)D, plasma or serum 25-hydroxyvitamin D; AIR, acute insulin release; D<sub>2</sub>, ergocalciferol; D<sub>3</sub>, cholecalciferol; DI, disposition index (an estimate of pancreatic beta-cell function); FG, fasting glucose; HbA1c, glycated hemoglobin A1c; HOMA%B, homeostatic model assessment for insulin secretion; HOMA-IR, homeostatic model assessment for insulin resistance; HR, hazard ratio; IFG, impaired fasting glucose; IU, international units; ND, no data; NS, not significant; QUICKI, quantitative insulin-sensitivity check index. To convert 25(OH)D concentration from ng/mL to nmol/L multiply by 2.459; to convert FG from mg/dL to mmol/L, multiply by 0.0555.

advanced). In these trials, study duration varied from 2 months to 7 years and doses ranged from 400 IU/day to 88,865 IU/weekly. Studies that tested yogurt fortified with vitamin D are excluded from the discussion due to potential confounding effects of yogurt [204,205]. Due to several study limitations (e.g., small sample size [as small as 15 participants], short duration, open-label), the quality of most trials that have examined the effects of vitamin D on outcomes related to type 2 diabetes is rated as poor or fair.

Among trials of healthy people with normal glucose tolerance at baseline, vitamin D had no appreciable effect on glycemic measures [206–219] or incident diabetes [208,220]. All trials in people with normal glucose tolerance were not powered for glycemic outcomes. The two largest trials among people with normal glucose tolerance used doses of vitamin D (400 IU/day [208] and 800 IU/day [220]) that are considered inadequate for changing the pathophysiology of type 2 diabetes. Overall, vitamin D appears to have no effect among people with normal glucose tolerance, which is not surprising because it is very difficult to demonstrate statistically or clinically significant improvements in glycemic variables (e.g., fasting glucose, Hemoglobin A1c)—that are within the normal range at baseline.

Among trials in participants with normal glucose tolerance that reported insulin resistance, there was no statistically significant differences between vitamin D and placebo [207–209,212–216,218,219,221]. In contrast, the study by Von Hurst et al. randomized nondiabetic South Asian women that had blood 25(OH)D < 20 mg/dL (mean 8 ng/mL) to 4000 IU/day of vitamin D<sub>3</sub> (n = 42) or placebo (n = 39) for 6 months, and there was a significant improvement in insulin resistance, assessed by HOMA-IR, with vitamin D compared with placebo, which was more evident when endpoint serum 25(OH)D reached 32 mg/dL. In another trial among healthy men with blood 25(OH)D < 20 ng/mL (mean 16 ng/mL), vitamin D at 100,000 IU twice a month for 1 year maintained HOMA-IR compared with rising values in the control group [217]. Overall, vitamin D appears to have little or no effect on insulin resistance among people with normal glucose tolerance, especially if blood 25(OH)D is higher than 20 ng/mL, which is not surprising because people with normal glucose generally do not have insulin resistance to begin with.

There are at least 16 trials where participants with established type 2 diabetes were randomized to ergocalciferol [222] or cholecalciferol [223,224] [225,226,227,228,229,230,231,232,233,234,235,236,237,238] versus placebo or vitamin C [226] (Table 76.2). Among these trials, there is significant heterogeneity in how vitamin D was administered, duration of follow-up, and how outcomes were ascertained. Seven trials gave vitamin D daily

[226–229,231,235,236]. The remaining trials gave vitamin D as high (40,000 to 400,000 IU), nondaily doses whose benefit has been questioned [239–241]. It is now believed that to optimize bodily function, including in relation to insulin secretion and sensitivity, vitamin D should be available on a daily basis to ensure adequate stable circulating concentrations of the parent molecule [241].

In most trials among people with established type 2 diabetes, there was no change in measures of glycemia (fasting glucose, hemoglobin A1c or 2-hour glucose after a 75-gram glucose challenge) with vitamin D after a follow-up period of 4 weeks to 1 year. Four trials reported favorable changes in hemoglobin A1c or fasting glucose in the group that was randomized to vitamin D [231,233,238]. What these trials have in common is that they recruited patients with stable, noninsulin requiring type 2 diabetes and low baseline blood 25(OH)D level (generally less than 20 ng/mL). Overall, results suggest that vitamin D may not have an appreciable effect on glycemia in people with established type 2 diabetes; however, firm conclusions from these trials cannot be drawn as the studies were underpowered and there was high heterogeneity in populations studies. Most importantly, given the multiple factors that can influence glycemia during a trial that can be difficult to control, an adequately powered (very large) study that carefully monitors and adjusts for potential confounders between active and placebo arms (e.g., concurrent hypoglycemic medications, lifestyle habits) is needed to test the effect of vitamin D among patients with type 2 diabetes. Such trial is unlikely to be conducted. The Thiazolidinedione Intervention with vitamin D Evaluation (TIDE) study was a 3 × 2 factorial design trial aimed to assess the effects of thiazolidinediones (rosiglitazone and pioglitazone) and 1000 IU/day of vitamin D<sub>3</sub> among 16,000 patients with type 2 diabetes in 33 countries [242]. The trial was expected to provide important data on the effect of vitamin D in people with type 2 diabetes; however, it was stopped prematurely because of regulatory concerns regarding the thiazolidinediones.

Two trials have reported the effect of combined vitamin D<sub>3</sub> and calcium supplementation versus placebo on glycemic measures and diabetes risk, both *post hoc*. In the WHI trial, vitamin D<sub>3</sub> (400 IU/day) and calcium supplementation (1000 mg/day) did not reduce the risk of developing self-reported diabetes over a 7-year period, and there was also no significant effect on fasting glucose or simple indices of insulin resistance [208]. The WHI trial used a small dose of vitamin D and allowed participants to take vitamin D supplements on their own during the trial. Although the effect of supplementation on blood 25(OH)D concentration was not reported, based on dose and adherence, it has been estimated it to be only 2 ng/mL [243], which is an increment

unlikely to have any effect. In the trial by Pittas et al. in the subgroup of participants with impaired fasting glucose at baseline, combined vitamin D<sub>3</sub> (700 IU/day) and calcium carbonate (500 mg/day) attenuated the increase in fasting glycemia that occurs over time in this population [207]. There was no effect on glycemia among participants with normal glucose tolerance at baseline, suggesting that vitamin D may benefit only individuals with prediabetes. In another trial by Pittas et al. among people with prediabetes [50], vitamin D and calcium were given in a 2 × 2 factorial design. When examining the group that was randomized to receive both vitamin D and calcium, there was a significant improvement in both hemoglobin A1c and fasting glucose, suggesting that combination of vitamin D and calcium may be important in the modulation of the pathophysiology of type 2 diabetes. However, the sample size was very small, and firm conclusions cannot be drawn on the importance of combining vitamin D with calcium to optimize diabetes outcomes.

In summary, vitamin D supplementation has not been shown to be of benefit in studies that included patients with normal glucose tolerance or established type 2 diabetes, but there appears to be a role in people at risk for diabetes (prediabetes). synthesis of the available evidence from trials on the effect of vitamin D on new-onset diabetes and regression to normal glucose regulation among people with prediabetes is presented in the next section.

## 6. Vitamin D for prevention of type 2 diabetes in people with prediabetes

### 6.1 Vitamin D and new-onset diabetes. Results from individual clinical trials

Thirteen trials published between 2008 and 2022 have reported on the effect of vitamin D on new-onset diabetes [4–6,208,220,244–251] (Table 76.3). Two large trials (WHI and RECORD) were designed and conducted for nondiabetes outcomes and reported data on new-onset diabetes in ancillary, post hoc analyses [208,220]. These two trials enrolled patients at average risk for diabetes, the intervention was low-dose vitamin D<sub>3</sub> (400 and 800 IU daily) coadministered with calcium in a 2 × 2 factorial design, and diabetes was ascertained by participant self-report based on a diagnosis made outside of the study in routine clinical practice. The remaining 11 trials that have reported data on the effect of vitamin D supplementation and incident diabetes recruited adults with prediabetes [4–6,244–251]. Seven of these trials have major limitations, including small sample size (90–205 participants) [244–251], not designed or powered for new-onset diabetes as the primary outcome [244–251], short duration

(=<1 year) [244,246–248,251], or open-label study design without placebo [245,247,249–251]. In most of these trials, including the two largest ones [208,220], adherence with supplementation was suboptimal, which further limit drawing any conclusions. For example, in a post hoc analysis of the RECORD study, a community-based effectiveness trial designed for bone outcomes, supplementation with 800 IU/day of vitamin D<sub>3</sub> did not change risk of self-reported diabetes; however, among participants who were highly adherent with supplementation, there was a notable trend toward reduction in diabetes risk with vitamin D<sub>3</sub> (odds ratio 0.68; 95% confidence interval 0.40, 1.16) [220], which highlights the difference of efficacy (where adherence is monitored and encouraged) versus effectiveness community-based trials when evaluating evidence. Overall, results from the two large trials (WHI, RECORD) [208,220] and these eight smaller trials [244–251] are not informative in our understanding of the role of vitamin D supplementation for prevention of type 2 diabetes in the clinical setting.

There have been three large, double-blind, placebo-controlled, randomized clinical trials designed and conducted specifically to test the hypothesis that vitamin D lowers the risk of developing diabetes among persons with prediabetes [4–6,252,253] (Table 76.4).

#### 6.1.1 The Tromsø study

The Tromsø study was a single-site trial that took place from March 2008 through March 2015 in Norway [5]. The study randomly assigned 511 adults (mean age 62 years, mean BMI 30 kg/m<sup>2</sup>) who met at least one of two glycemic criteria for prediabetes (fasting glucose 108–125 mg/dL; glucose 2 h post 75-gram oral glucose load 140–199 mg/dL) and had no diabetes (fasting glucose <126 mg/dL and hemoglobin A1c <6.5%) to treatment with 20,000 IU of vitamin D<sub>3</sub> weekly (equivalent to ~2900 IU per day) or placebo. Blood 25(OH)D level was not an eligibility criterion. The primary outcome was time to new-onset diabetes based on annual glycemic testing through fasting glucose, hemoglobin A1c, and 2-hour glucose. The study had 80% power to detect a risk reduction in new-onset diabetes of 30% with vitamin D compared with placebo. Mean baseline blood 25(OH)D level was 24 ng/mL, and 68% of participants had a blood 25(OH)D level ≥20 ng/mL (Table 76.4). During follow-up, mean blood 25(OH)D level in the vitamin D group rose to 44 ng/mL compared with 26 ng/mL in the placebo group. After a median follow-up of 2.5 years, 103 participants developed diabetes in the vitamin D group versus 112 in the placebo group (11.8 events vs. 13.1 events per 100 person-years, respectively). In the intention-to-treat analysis, the risk of diabetes was 10% lower in the vitamin D group, but the result was not statistically significant (hazard ratio for vitamin D 0.90; 95% confidence interval

**TABLE 76.3** Trials that have reported on the effect of vitamin D and new-onset diabetes or regression to normal glucose regulation.

First author year of publication (country)	Target population (n = number of participants)	Baseline 25(OH)D concentration, ng/mL	Interventions (number of participants)	Study duration, years	Study quality (reasoning)	Designed for glycemic outcomes, (Yes/ No)	Primary outcome(s)	Other glycemic outcomes?	Was the trial designed, conducted for the primary prevention of type 2 diabetes, i.e., was new-onset diabetes the primary outcome?
<i>Populations at average risk for type 2 diabetes – not designed for glycemic outcomes or for primary prevention of type 2 diabetes</i>									
De Boer (2008) (US)	Healthy, postmenopausal women (n = 33,951)	Not available	D <sub>3</sub> 400 IU daily plus calcium carbonate 1,000 mg daily (n = 16,999) versus placebo (n = 16,952)	Median of 7 years	Fair (post hoc analysis, self- report of new- onset diabetes, single gender)	No	- Fracture reduction	- New-onset diabetes	No
Avenell (2009) (UK)	Healthy adults ≥70 years and history of fracture (n = 5,292)	Not available	D <sub>3</sub> 800 IU daily (n = 2,649) versus placebo (n = 2,643) (2 × 2 factorial design with calcium carbonate 1,000 mg daily)	Range of 2–5 years	Fair (post hoc analysis, self- report of new- onset diabetes)	No	- Fracture reduction	- New-onset diabetes	No
<i>Populations at risk for type 2 diabetes (prediabetes) – not designed for primary prevention of type 2 diabetes</i>									
Davidson (2013) (US)	Prediabetes by FG or 2 hG, and 25(OH) D < 30 ng/mL (n = 109)	22	Treat-to-target 25(OH)D 65 –90 ng/mL, mean D <sub>3</sub> 88,865 IU weekly (~12,695 IU daily) (n = 56) versus placebo (n = 53)	Up to 1 year	Moderate (small sample size)	Yes	- OGTT-based insulin sensitivity and secretion	- New-onset diabetes - NGR	No
Dutta (2014) (Eastern India)	Prediabetes by FG or 2 hG, and 25(OH) D < 30 ng/mL (n = 125)	17	D <sub>3</sub> 60,000 IU weekly (~8,571 IU daily) for 8 weeks, then 60,000 IU monthly (~3,000 IU daily) (n = 68) versus no treatment (n = 57) (open label). All received calcium 500 mg daily	Mean of 2.3 years	Poor (small sample size, open label, unclear methodology section)	Yes	- New-onset diabetes - NGR	- FG - 2 hG	No

Barengolts (2015) (US)	Black men with prediabetes (84%) or diabetes (16%) based on FG or HbA1c, and 25(OH)D 5–29 ng/mL, and prevalent medical problems (n = 205)	14	D <sub>2</sub> 50,000 IU weekly (~7,143 IU daily) adjusted to achieve 25(OH)D 40–100 ng/mL (n = 103) versus placebo (n = 102). All received D <sub>3</sub> 400 IU daily	Up to 1 year	Fair (small sample size, single race and gender; both prediabetes and diabetes populations)	Yes	- OGTT-based oral glucose insulin sensitivity	- New-onset diabetes - NGR - OGTT-based insulin secretion - HbA1c	No
Kuchay (2015) (North India)	Prediabetes by FG, 2 hG, or HbA1c (n = 137)	19	D <sub>3</sub> 60,000 IU weekly (~2,000 IU daily) for 4 weeks, then monthly (n = 69) versus no treatment (n = 68) (open label)	Up to 1 year	Poor (small sample size, open label)	Yes	- FG - 2 hG - HbA1c	- New-onset diabetes	No
Niroomand (2019) (Iran)	Prediabetes based on FG or 2 hG, and 25(OH)D < 30 ng/mL (n = 162)	13	D <sub>3</sub> 50,000 IU weekly (~7,143 IU daily) for 3 months, then monthly (n = 81) versus placebo (n = 81)	Up to 6 months	Poor (small sample size, completers only analysis [50% of randomized])	Yes	- Insulin sensitivity	- New-onset diabetes - NGR - FG - 2 hG	No
Bhatt (2020) (India)	Prediabetes based on FG or 2 hG, and 25(OH)D < 20 ng/mL (n = 121)	12	D <sub>3</sub> 60,000 IU weekly (~3,571 IU daily) for 8 weeks and repeated as needed to "avoid deficiency," then 200 IU daily (n = 61) versus placebo (n = 60) (open label). All received calcium carbonate daily	18 months	Poor (small sample size, open label)	Yes	- FG - 2 hG - HbA1c - New-onset diabetes - NGR		No
Misra (2021) (Northern India)	Prediabetes based on FG or 2 hPG and 25(OH)D < 30 ng/mL	23	D <sub>3</sub> 60,000 IU weekly (~8,571 IU daily) for 8 weeks, repeated if needed to reach 25(OH)D > 30 ng/mL (n = 67) versus placebo (n = 65) (open label)	Up to 2 years	Poor (small sample size, open label)	Yes	- New-onset diabetes	- NGR - FG - 2 hG - HbA1c	No

Comparator	Placebo daily	Placebo daily	Placebo daily
Vitamin D amount from supplements allowed outside of the study	≤400 IU/day	≤1000 IU/day	No vitamin D from supplements was allowed
Definition of primary outcome, new-onset diabetes	Any glycemic-positive criteria: FG ≥ 126 mg/dL, 2 hG ≥ 200 mg/dL, HbA1c ≥ 6.5%. A positive HbA1c required confirmation	Two or three glycemic-positive criteria: FG ≥ 126 mg/dL, 2 hG ≥ 200 mg/dL, HbA1c ≥ 6.5%, or 1 criterion positive with confirmation	HbA1c ≥ 6.5% and either: FG ≥ 126 mg/dL, 2 hG ≥ 200 mg/dL, or casual glucose ≥ 200 mg/dL
Expected incidence of diabetes in the placebo group, per 100 person-years	10.0	10.5	8.4
Expected relative risk reduction in diabetes, vitamin D versus placebo, %	30	25	36
Median (interquartile range) (range) follow-up, years <sup>b</sup>	4.0 (1.5–5.0) (0.2–5.2)	2.5 (1.9–3.5) (0–4.7) (event-driven)	2.9 (2.8–3.0) (0.1–3.0)
Hazard ratio (95% confidence interval) for new-onset diabetes, vitamin D versus placebo	0.90 (0.69–1.18)	0.88 (0.75–1.04)	0.87 (0.67–1.17)

<sup>a</sup>Tromsø had 1 site in Norway (University Hospital of North Norway at 70° North latitude); D2d had 22 sites (22 different locations) in the United States (12 sites were above 37° North latitude and 10 sites were below 37° North latitude); DPVD had 3 sites at 2 locations in Japan (Fukuoka location at 34° North latitude and Kanagawa location at 35° North latitude).

<sup>b</sup>The Tromsø study was designed to follow participants up to 5 years or until the diagnosis of diabetes. The D2d study was designed as an event-driven trial and follow-up, as expected, varied among participants. The DPVD study was designed to follow participants up to 3 years or until the diagnosis of diabetes.

2 hG, glucose 2 h after a 75-gram oral glucose load; FG, fasting glucose; HbA1c, hemoglobin A1c; iA1c, impaired hemoglobin A1c; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

0.69–1.18) [5]. The authors reported that among participants with a rise in blood 25(OH)D from less than 20 ng/mL to more than 32 ng/mL, there was a larger risk reduction (21%), but the change was also not statistically significant due to the small number of participants in this subgroup (hazard ratio for vitamin D 0.79; 95% confidence interval 0.46–1.37).

### 6.1.2 The vitamin D and type 2 diabetes study

The D2d study was the largest vitamin D and diabetes prevention trial with 22 sites in the United States and took place from October 2013 through December 2018 (Fig. 76.5) [4,253]. The study, which was supported by the National Institutes of Health, randomly assigned 2423 adults (mean age 60 years, mean BMI 32.1 kg/m<sup>2</sup>)

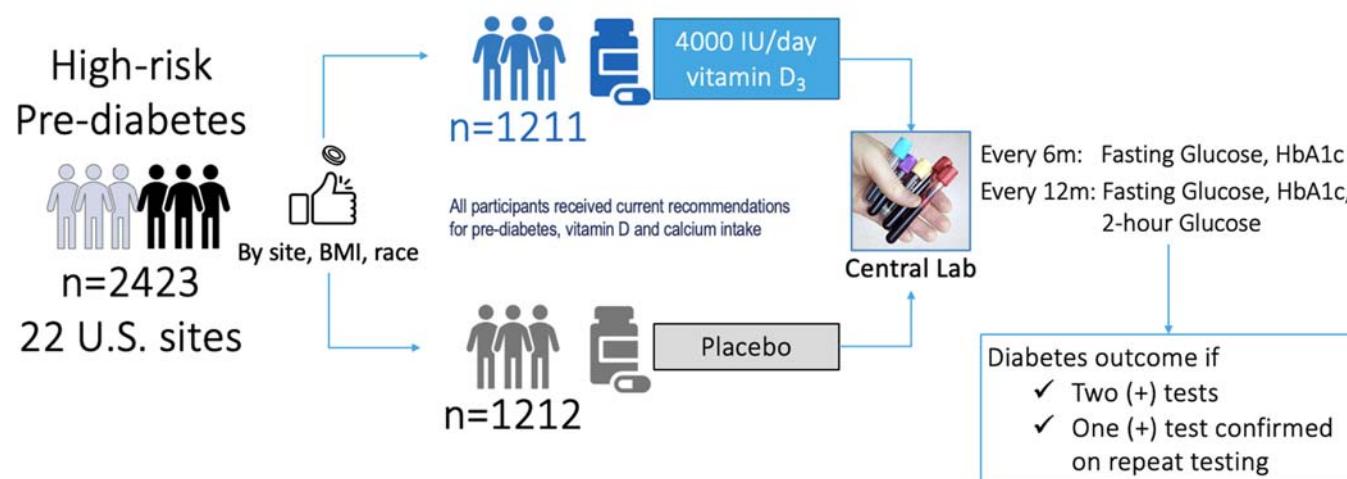

FIGURE 76.5 Overview of the design of the vitamin D and type 2 diabetes (D2d) study.

who met at least two of three glycemic criteria for pre-diabetes (fasting glucose 100–125 mg/dL; glucose 2 h post 75-gram oral glucose load 140–199 mg/dL; hemoglobin A1c 5.7%–6.4%) to treatment with 4000 IU of vitamin D<sub>3</sub> daily or placebo. The primary outcome was time to new-onset diabetes based on annual glycemic testing through fasting glucose, hemoglobin A1c, and 2-hour glucose, and semiannual testing with fasting glucose and hemoglobin A1c. The D2d study was designed as an event-driven trial, and blood 25(OH)D level was not an eligibility criterion. The study had 90% power to detect a risk reduction in new-onset diabetes of 25% with vitamin D compared with placebo. Mean baseline blood 25(OH)D level was 28.0 ng/mL, and 78% of participants had a 25(OH)D level  $\geq 20$  ng/mL (Table 76.4). At baseline, 84% of participants met both fasting glucose and hemoglobin A1c criteria for prediabetes, which are the most commonly criteria for prediabetes used in clinical practice. During follow-up, mean blood 25(OH)D level in the vitamin D group rose to 54 ng/mL compared with 29 ng/mL in the placebo group. After a median follow-up of 2.5 years, 293 participants in the vitamin D group developed diabetes versus 323 in the placebo group (9.39 events vs. 10.66 events per 100 person-years, respectively). In the intention-to-treat analysis, the risk of diabetes was 12% lower in the vitamin D group, but the result was not statistically significant (hazard ratio for vitamin D 0.88; 95% confidence interval 0.75–1.04) [4]. The results of the subgroup analyses were consistent with the findings of the main analysis, i.e., favoring vitamin D but without statistically significant heterogeneity among subgroup (Fig. 76.6), except among participants with a baseline 25(OH)D level  $< 12$  ng/mL (103 participants), where vitamin D reduced the risk of developing diabetes by

62% (hazard ratio for vitamin D 0.38; 95% confidence interval 0.18–0.80) (Fig. 76.7).

### 6.1.3 Diabetes prevention with active vitamin D study

The DPVD study was a three-site trial that took place from June 2013 through August 2019 in Japan [6,252]. The study randomly assigned 1256 adults (mean age 61 years, mean BMI 24 kg/m<sup>2</sup>) who met the impaired glucose tolerance criterion for prediabetes (glucose 2 h post 75-gram oral glucose load 140–199 mg/dL) and had no diabetes (fasting glucose  $< 126$  mg/dL and hemoglobin A1c  $< 6.5\%$ ) to treatment with 0.75 mg of eldcalcitol (an analog of calcitriol, the active form of vitamin D<sub>3</sub>) daily or placebo. Blood 25(OH)D level was not an eligibility criterion. The primary outcome was time to new-onset diabetes based on annual glycemic testing through fasting glucose, hemoglobin A1c, and 2-hour glucose and quarterly glycemic testing with fasting glucose and hemoglobin A1c. The study had 80% power to detect a risk reduction in new-onset diabetes of 36% with vitamin D compared with placebo. Mean baseline blood 25(OH)D level was 21 ng/mL, and 56% of participants had a 25(OH)D level  $\geq 20$  ng/mL (Table 76.4). During follow-up, mean blood 25(OH)D level did not change in the vitamin D or placebo groups, as expected because eldcalcitol is the active form of vitamin D<sub>3</sub>. After a median follow-up of 2.9 years, 79 participants developed diabetes in the vitamin D group versus 89 in the placebo group (12.5 vs. 14.2%, respectively). In the intention-to-treat analysis, the risk of diabetes was 13% lower in the vitamin D group, but the result was not statistically significant (hazard ratio for vitamin D 0.87; 95% confidence interval 0.67–1.17).

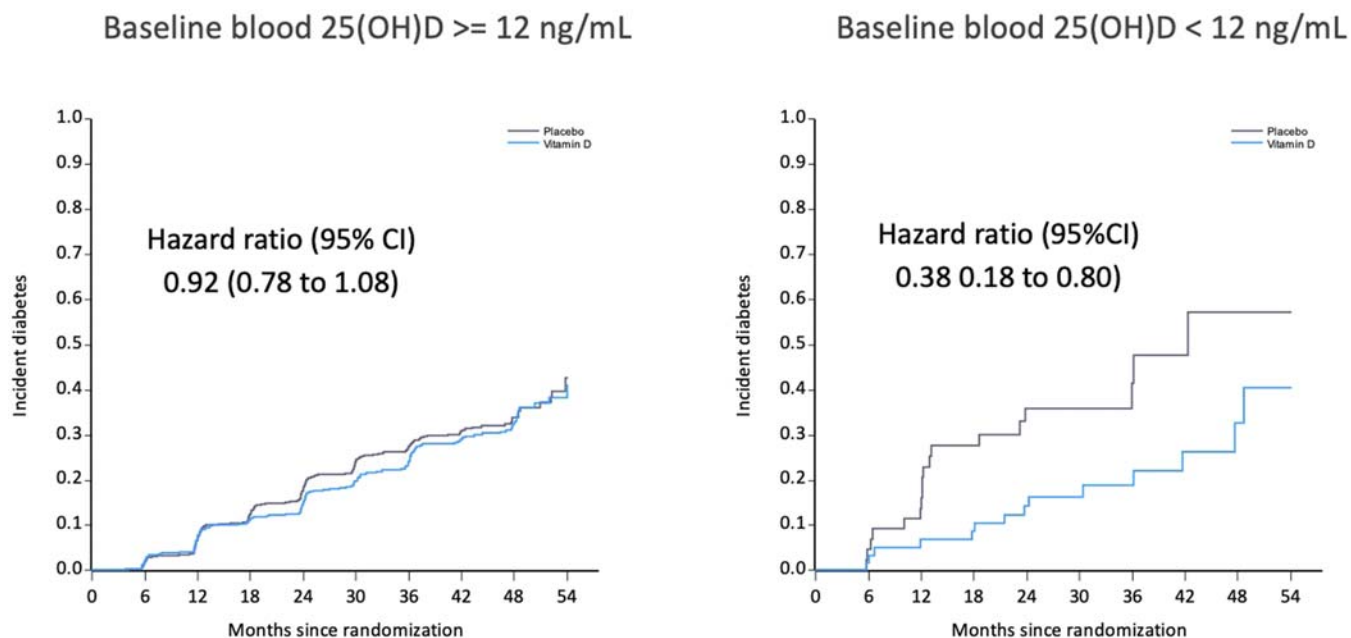

**FIGURE 76.6** Hazard ratios for new-onset diabetes in the vitamin D and type 2 diabetes (D2d) study in pre-defined subgroups of participants defined by baseline characteristics. From Figure 3 in Ref. [4].

[6]. After adjustment for confounding factors by multi-variable fractional polynomial Cox regression analysis, there was a statistically significant reduction in the risk of developing diabetes of 31% in the eldecacitol group compared with the placebo group (hazard ratio for vitamin D 0.69, 95% confidence interval 0.51–0.95). Eldecacitol had a significant effect on diabetes risk among those with insufficient insulin secretion.

#### 6.1.4 Other large trials

Except for the Tromsø, DPVD, and D2d studies, there are no other vitamin D and diabetes prevention trials that have been specifically designed and conducted to

test the effect of vitamin D on reducing risk of developing type 2 diabetes. There are several large trials testing the effect of vitamin D supplementation on non-diabetes outcomes (e.g., The VITamin D and Omega-3 Trial [VITAL] [254], D-Health [255], the Finnish Vitamin D Trial (FIND, NCT01463813) [256] in populations at average risk for diabetes, and these trials may report results on diabetes risk, based on ancillary secondary analyses. However, results will have the same limitations as all other trials that are not designed for diabetes prevention (e.g., enrollment of populations at average risk for diabetes, inadequate vitamin D dose, and insufficiently defined and ascertained diabetes outcome).

**FIGURE 76.7** Hazard ratio for new-onset diabetes in the vitamin D and type 2 diabetes (D2d) study among participants with prediabetes and baseline blood 25(OH)D  $\geq 12$  ng/mL (left panel, N = 2319) or baseline blood 25(OH)D  $< 12$  ng/mL (right panel, N = 103). Nominal *P*-value for the interaction term = .023.

## 6.2 Vitamin D and new-onset diabetes. Results from aggregate (study-level) data metaanalyses

Two metaanalyses have combined aggregate (study-level) data from vitamin D supplementation trials that have reported on new-onset diabetes [2,257].

Zhang et al. synthesized results from eight trials (total of 4896 participants, sample sizes ranging from 117 to 2423; duration of follow-up 6 months to 5 years) in persons with prediabetes. Three of the included trials had a low risk for bias (Tromsø, D2d, and DPVD) [4–6], and the rest had either unclear or high risk of bias. The authors reported a benefit of vitamin D for new-onset diabetes (risk ratio 0.89; 95% confidence interval 0.80–0.99) [257]. There was no publication bias. In subgroup analyses, the benefit was prominent when combining aggregate results from trials that had a mean baseline nonobese BMI ( $<30$  kg/m<sup>2</sup>) (risk ratio 0.73; 95% confidence interval 0.75–0.92) versus trials that had a mean baseline obese BMI (risk ratio 0.95; 95% confidence interval 0.84–1.08). The authors did not find any interaction according to mean baseline 25(OH)D, achieved 25(OH)D in vitamin group, dose of vitamin D, length of follow-up, intervention, or latitude. Overall, the authors concluded that in people with prediabetes, vitamin D reduces the risk of developing type 2 diabetes.

Barbarawi et al. synthesized results from nine trials (total of 43,559 participants; sample sizes ranging from 1109 to 33,951; duration of follow-up 1–7 years) that reported the effect of vitamin D for at least 1 year on

new-onset diabetes [2]. Two trials (WHI, RECORD) (total of 39,243 participants) were designed and conducted for nondiabetes outcomes (fracture reduction) in persons of average diabetes risk who were randomized to low-dose vitamin D ( $<1000$  IU per day) and the trials reported data on new-onset diabetes in post hoc analyses [208,220]; seven trials (total of 4316 participants) were in persons with prediabetes randomized to moderate–high doses of vitamin D ( $\geq 1000$  IU per day). The authors reported a benefit of vitamin D for new-onset diabetes when combined data from the trials among persons with prediabetes who also received moderate–high doses of vitamin D (risk ratio 0.88; 95% confidence interval 0.79–0.99). In contrast, when combining data from the trials that tested lower doses, which were also conducted in the general average-risk-for-diabetes population, there was no risk reduction with vitamin D (risk ratio 1.02; 95% confidence interval 0.94–1.10; *P* for interaction = 0.04). There was no publication bias. Like the metaanalysis by Zhang et al. the authors reported that the benefit of vitamin D was seen when combining trials that had a mean baseline nonobese BMI ( $<30$  kg/m<sup>2</sup>) (risk ratio 0.68; 95% confidence interval 0.53–0.89), while there was no benefit among trials with a mean baseline BMI  $\geq 30$  kg/m<sup>2</sup>. Subgroup analysis according to baseline mean age, gender, formulation (daily vs. bolus dosing), and low mean baseline blood 25(OH)D level did not reveal any significant modifying effects. Overall, the authors concluded that in people with prediabetes, vitamin D at moderate or high doses ( $\geq 1000$  units per day) reduces the risk of developing type 2 diabetes.

Metaanalyses have increased in popularity, but even if the methodology is sound, the strength of a metaanalysis result depends on the quality of the included individual trials. Most importantly, for metaanalyses to draw appropriate conclusions, they must combine data from trials that have been specifically designed and conducted to answer the question at hand. Although the metaanalyses by Zhang et al. and Barbarawi et al. used data from clinical trials, there are many limitations. Trials that simply report on incident diabetes as a secondary outcome do not carry the same weight as trials that have been specifically designed and conducted to test the hypothesis that vitamin D supplementation reduces diabetes risk. For example, the WHI study was a “mega” trial that used a relatively small dose of vitamin D and was designed and conducted to test nondiabetes outcomes in a population at average risk for diabetes and assessed the diabetes outcome by participant’s self-report of taking pills or insulin for diabetes. Therefore, including trials such as the WHI in metaanalyses of vitamin D and diabetes prevention trials is methodologically inappropriate, and given their large size, results would dilute the overall result of the metaanalysis, leading to inappropriate conclusions. In fact, except for three trials (Tromsø, D2d, and DPVD) [4–6], all other trials that were in both these metaanalyses were also not designed for diabetes prevention.

Interestingly, both metaanalyses reported on the effects of vitamin D in subgroups by baseline BMI cutoffs; however, such a subgroup claim is highly problematic and may be erroneous (subject to ecological fallacy) because the authors generated analyses based on the average BMI of each trial cohort rather than the BMI of each participant [89]. For example, trials with mean baseline BMI  $<30$  kg/m<sup>2</sup> include participants with BMI  $\geq 30$  kg/m<sup>2</sup> in both vitamin D and placebo groups and using the mean cohort BMI to gain insight into whether vitamin D works differentially among people with different BMI is methodologically flawed. The same limitations apply to the subgroup analyses according to other variables at baseline (e.g., age, blood 25(OH)D levels). In the absence of individual participant data, most results from subgroups analyses in aggregate data metaanalyses are uninterpretable.

Due to similar limitations, results by the recent USPSTF report on the effect of vitamin D on diabetes risk in people with vitamin D deficiency are not informative [258]. The USPSTF report pooled data from five highly heterogeneous trials (varied interventions [vitamin D or vitamin plus calcium], study populations [prediabetes or average risk], and outcome assessments [in-study diagnosis, self-report, or as adverse event] and did not include the DPVD study, the second largest vitamin D and diabetes prevention trial.

### 6.3 Vitamin D and new-onset diabetes. Results from individual participant data metaanalysis

In contrast to an aggregate data metaanalysis, an individual participant data metaanalysis offers several advantages: increased statistical power to detect benefits and risks, higher precision of results (i.e., narrower 95% confidence interval), ability to conduct a detailed analysis including sensitivity analyses to test the robustness of results, define more precisely participant cohorts and standardize covariate definitions, and harmonize analyses to attenuate methodological heterogeneity; establish differences among important subgroups by baseline characteristics, which allows for identification of segments of the population most likely to benefit from supplementation [259–263].

Pittas et al. conducted a systematic review of the published literature and performed an individual participant data metaanalysis strictly of randomized, placebo-controlled trials of vitamin D—only among adults with prediabetes to assess whether vitamin D decreases the risk of new-onset diabetes and whether the effect differs across prespecified subgroups of participants [264].

Three trials met eligibility criteria: Tromsø (tested cholecalciferol), DPVD (tested eldecalcitol), and D2d (tested cholecalciferol) studies [4–6]. All 4190 participants from the three trials contributed data to the metaanalysis (N = 2097 were randomly assigned to receive vitamin D and N = 2093 to receive placebo). Mean age of the combined cohort with prediabetes was 61 years; 44% were women, 51% self-identified their race as White or European 33% as Asian, and 15% as Black. Mean BMI was 30 kg/m<sup>2</sup>, and mean serum 25(OH)D level was 25 ng/mL.

During a median follow-up of 3.0 years, new-onset diabetes occurred in 22.7% of participants in the vitamin D versus 25.0% in the control group (Fig. 76.8). The unadjusted hazard ratio for vitamin D was 0.88 (95% confidence interval 0.77–0.99) in the intention-to-treat analysis and 0.85 (95% confidence interval 0.75–0.97) in the “as treated” (efficacy) analysis. Adjusted hazard ratios were 0.85 (95% confidence interval 0.75–0.96) in the intention-to-treat and 0.83 (95% confidence interval 0.73–0.94) in the “as treated” analysis. The effect of vitamin D (cholecalciferol or eldecalcitol combined) did not differ in prespecified subgroups. The effect of vitamin D on new-onset diabetes did not differ by baseline age, BMI, gender, race, glycemic risk, or calcium intake from supplements. Among the 224 participants with baseline 25(OH)D level less than 12 ng/mL, the vitamin D reduced the risk of diabetes by 62% (hazard ratio 0.58 [95% CI 0.35–0.97]). When the authors examined data from the two trials that administered

**FIGURE 76.8** Incidence curves for new-onset diabetes among adults with prediabetes: intention to treat analysis of individual participant data from the three vitamin D and diabetes prevention trials (Tromsø, D2d, DPVD). From Figure 2 in Ref. [273].

cholecalciferol, which requires activation to 25(OH)D in the liver and elsewhere by CYP2R1 [4,5], the effect of cholecalciferol on new-onset diabetes was noted only in participants with below median BMI (hazard ratio 0.74 [95% confidence interval 0.60–0.90] for BMI <31 versus 1.01 [95% confidence interval 0.84–1.22] for BMI ≥31 kg/m<sup>2</sup>).

The key strength of this individual participant data metaanalysis lies in the high quality of the included clinical trials, all being double-blinded, randomized, placebo-controlled, and at low risk of bias. Most importantly and in contrast to other metaanalyses in this area that combined data from trials with high-risk for bias [2,257], the eligible trials in this metaanalysis were specifically designed and conducted for diabetes prevention, used modern definitions of prediabetes to define the at-risk-for-diabetes study populations, had adequate long-term follow-up, and ascertained the primary outcome of new-onset diabetes by prespecified glycemic criteria, as defined by the American Diabetes Association or the World Health Organization.

#### 6.4 Vitamin D and regression to normal glucose regulation. Results from individual clinical trials

Although diabetes prevention trials focus on delaying progression from prediabetes to diabetes, regression to normal glucose regulation is an important clinical outcome because euglycemia is associated with a lower

prevalence of microvascular disease compared with prediabetes, likely due to less long-term exposure to abnormal glucose levels and because even transient regression to normal glucose regulation confers lower risk of developing diabetes [264–266]. In addition to reducing progression from prediabetes to diabetes, vitamin D increases the likelihood of regression to normal glucose regulation based on evidence from the three vitamin D and type 2 diabetes prevention trials [4–6], and from smaller trials [244–246,248–251] (Table 76.3).

In the D2d study, participants randomized to vitamin D were 31%–45% (depending on the definition of normal glucose regulation used) more likely to have reached normal glucose regulation at their last visit compared with those randomized to placebo. Specifically, when regression to normal glucose regulation was defined as two or three American Diabetes Association glycemic criteria in the normal range (fasting glucose <100 mg/dL, hemoglobin A1c <5.7%, or 2-hour post 75-gram load glucose less than 140 mg/dL) and none in the diabetes range, 12.4% in the vitamin D versus 9.5% in the placebo group had regressed to normal glucose regulation at the last visit over a median follow-up of 2.5 years (rate ratio for vitamin D 1.31; 95% confidence interval 1.02–1.70). When normal glucose regulation was defined as having both fasting glucose and 2-hour post 75-gram load glucose in the normal range (<100 mg/dL and <140 mg/dL, respectively) regardless of hemoglobin A1c, 8.7% of participants in the vitamin D versus 6.0% in the placebo group had regressed to normal glucose regulation at the last visit (rate ratio for vitamin D 1.45; 95% confidence interval 1.05–2.00).

The other two large vitamin D and diabetes prevention trials used slightly different definitions of normal glucose regulation and reported results in the same direction toward benefit; however, results were not statistically significant likely because of smaller sample size compared with the D2d study. In the Tromsø study, normal glucose regulation was defined as having both fasting glucose and 2-hour post 75-gram load glucose in the normal range (<108 mg/dL (6 mmol/L) and <140 mg/dL, respectively) regardless of hemoglobin A1c. By the end of the study, 55 (21.5%) of 256 participants in the vitamin D group and 41 (16.1%) of 255 in the placebo group had achieved normal glucose regulation [5]. In the DPVD study, normal glucose regulation was defined as meeting all three glycemic criteria: hemoglobin A1c <6.5%, fasting glucose concentration <110 mg/dL (6.1 mmol/L), and 2-hour post 75-gram load glucose concentration <140 mg/dL—or both of the following criteria: hemoglobin A1c <5.7% and fasting glucose <100 mg/dL. By the end of the study, 145 (23.0%) of 630 participants in the eldcalcitol

group, and 126 (20.1%) of 626 in the placebo group had achieved normal glucose regulation (hazard ratio 1.15, 95% confidence interval 0.93–1.41) [6].

In addition to the aforementioned three diabetes prevention trials, seven other trials [244–246,248–251] have reported on the effect of vitamin D and regression to normal glucose regulation in people with prediabetes and most have reported favorable effects with vitamin D. In a 1-year trial in the United States among adults with prediabetes and blood 25(OH)D level below 30 ng/mL (mean 22 ng/mL), vitamin D<sub>3</sub> at a mean dose of 88,865 IU weekly in a treat-to-target approach had no effect on rate of regression to normal glucose regulation (38% in vitamin D vs. 41% in placebo) [244]. In an open-label trial in Eastern India among adults with prediabetes and blood 25(OH)D level below 30 ng/mL (mean 17 ng/mL), 60,000 IU weekly of vitamin D<sub>3</sub> for 8 weeks, then monthly for 2 years, improved the likelihood of normoglycemia (42% for vitamin D vs. 20% for placebo) [245]. In a 1-year trial in the United States among Black adults with prediabetes and blood 25(OH)D level below 30 ng/mL (mean 14 ng/mL), vitamin D<sub>2</sub> at 50,000 IU weekly resulted in more participants in the vitamin D returning to normal glucose regulation versus the placebo (32% vs. 8%, respectively) [246]. In a 6-month trial in Iran among adults with prediabetes and blood 25(OH)D levels below 30 ng/mL (mean 13 ng/mL), vitamin D<sub>3</sub> at 50,000 IU weekly resulted in a higher rate of regression to normal glucose regulation (56% for vitamin D vs. 32% for placebo) [248]. In an open-label 78-week trial among overweight/obese Asian Indian women with prediabetes and blood 25(OH)D levels below 20 ng/mL (mean 12 ng/mL), vitamin D<sub>3</sub> at 60,000 IU weekly of vitamin D<sub>3</sub> in a treat-to-target approach improved the likelihood of normoglycemia (59% for vitamin D vs. 29% for placebo based on fasting glucose; 51% for vitamin D vs. 44% for placebo based on 2-hour glucose) [249]. In a 2-year community-based trial in Northern India among rural women with prediabetes and blood 25(OH)D levels below 30 ng/mL (mean 23 ng/mL), vitamin D<sub>3</sub> at 60,000 units per week in a treat-to-target approach increased the number of women with normoglycemia (23 out of 58 for vitamin D vs. 20 out of 58 for placebo) [250]. In a 1-year trial in Greece among people older than 75 years with prediabetes and mean blood 25(OH)D levels of 20 ng/mL, vitamin D<sub>3</sub> at 25,000 units weekly significantly increased the likelihood of participants returning to normoglycemia (17% for vitamin D vs. 0% for placebo) [251].

Overall, the findings from trials show a highly consistent effect of vitamin D in people with prediabetes towards increasing the likelihood of regression to normal glucose regulation.

## 6.5 Vitamin D and regression to normal glucose regulation. Results from metaanalyses

The results from the individual trials on the effect of vitamin D supplementation on regression to normal glucose regulation are consistent with the results from systematic reviews and metaanalyses, which also reported a higher likelihood of reversal to normal glucose regulation with vitamin D. In a metaanalysis using aggregate (study-level) data, Zhang et al. synthesized results from five trials totaling 1080 participants with prediabetes that reported the rate of reversion from prediabetes to normoglycemia [5,244–246,248]. The authors reported a significant benefit of vitamin D for regression to normal glucose regulation by 48% compared with placebo (risk ratio 0.89; 95% confidence interval 0.80–0.99), and results were consistent among different subgroups [257]. The authors concluded that in people with prediabetes, vitamin D increases the reversion rate of prediabetes to normoglycemia.

The metaanalysis by Pittas et al. with individual participant data from the three large randomized, placebo-controlled trials of vitamin D—only among adults with prediabetes [4–6] also assessed whether vitamin D promotes regression to normal glucose regulation. During a median follow-up of 3.0 years, 14.4% of participants in the vitamin D group (cholecalciferol or eldcalcitol combined) compared with 11.1% in the placebo group had regressed to normal glucose regulation at the last study visit (incident rate ratio 1.30; 95% confidence interval 1.16–1.46).

Based on the consistency of results from the metaanalyses using aggregate or individual participant data, when evaluating the overall benefit of vitamin D in prediabetes, the benefit of higher likelihood of reversal to normal glucose regulation should be added to the lower risk of progression to diabetes.

## 7. Optimizing blood 25(OH)D levels and the concept of “treat-to-target”

In observational cohort studies, people with the lowest blood 25(OH)D level have the highest risk of developing type 2 diabetes. However, as noted earlier, such an association may be due to confounding as people with low blood 25(OH)D level have other risk factors for type 2 diabetes, such as poor diet, overweight, and physical inactivity. Therefore, evidence from trials is necessary to test whether people at risk for type 2 diabetes and very low blood 25(OH)D level benefit the most from vitamin D.

In the D2d study, participants with a baseline 25(OH)D level of less than 12 ng/mL, which is the threshold

that defines vitamin D deficiency according to the National Academy of Medicine, randomized to vitamin D had a 62% lower risk of developing diabetes compared with placebo (Fig. 76.7) [4]. This result should be interpreted cautiously given the small sample size of the subgroup; however, the effect size was very large, and it is consistent with the dose–response curve expected for vitamins [267] and also consistent with additional evidence from mechanistic studies. In the same subgroup of D2d participants with low baseline 25(OH)D level, vitamin D improved the disposition index [52], indicating a large benefit in beta-cell function among those with very low 25(OH)D levels to begin with, consistent with the clinical result of lower diabetes risk in the same subgroup. Overall, results from observational studies and trials agree that in people with prediabetes, avoiding very low 25(OH)D levels reduces risk of developing type 2 diabetes.

In observational cohort studies, higher blood 25(OH)D levels are associated with lower risk of developing type 2 diabetes, as described earlier. For example, in a nested case–control study design in the NHS cohort of women, those in the top quartile of blood 25(OH)D (mean 33 ng/mL) had a 48% lower risk of developing diabetes compared with those in the bottom quartile (mean 14 ng/mL) [170]. Spline regression models showed a progressive decrease in risk within the higher 25(OH)D range ( $\sim 50$  ng/mL) with no apparent threshold for the relationship between 25(OH)D level and incident diabetes (Fig. 76.3). In a longitudinal observational study in the Diabetes Prevention Program (DPP) among participants with prediabetes, blood 25(OH)D levels were measured annually, and an integrated measure of intrastudy vitamin D status value for each participant was calculated as the predictor variable [193]. Participants in the DPP study who maintained a mean intrastudy blood 25(OH)D level of 30 ng/mL had 28% lower risk of developing diabetes compared with those who maintained intrastudy blood 25(OH)D levels of 13 ng/mL. There was no apparent threshold for the relationship between 25(OH)D level and incident diabetes, and the shape of the curve also suggested a stronger decrease in diabetes risk for 25(OH)D levels above  $>50$  ng/mL although very few participants had that level. Findings in the NHS and DPP cohorts are fully concordant with those from other observational longitudinal studies that have reported on the association between higher blood 25(OH)D and lower risk of developing type 2 diabetes. When combined such data in a metaanalysis, results show that higher 25(OH)D levels ( $>40$  ng/mL) conferred lower risk of developing diabetes, with no apparent plateau for benefit (Fig. 76.4) [189].

The results from the observational studies raise the possibility that in addition to avoiding low blood 25(OH)D levels, achieving and maintaining high blood 25(OH)D levels would optimize diabetes risk reduction. In the D2d study, repeated measures of blood 25(OH)D throughout the trial provided a unique opportunity to test whether achieving and maintaining high intratrial vitamin D levels influenced risk of developing diabetes. For each participant, intratrial vitamin D exposure was calculated as the mean of all annual serum 25(OH)D values prior to the occurrence of the primary endpoint of new-onset diabetes, start of a diabetes or weight-loss medication, or last follow-up visit. Participants who stopped taking their study pills and those who took vitamin D outside of the study were included in this analysis. Thus, this analysis captured incomplete adherence to the assigned treatment and use of off-protocol vitamin D. Categories of participants defined by their achieved intratrial 25(OH)D level were established using National Academy of Medicine cutoffs, and hazard ratios for diabetes among participants in each intratrial 25(OH)D category were estimated compared with the 20–29 ng/mL category (considered “sufficient” for bone health by the National Academy of Medicine) [268]. Results showed a significant interaction of treatment assignment (vitamin D or placebo) with intratrial 25(OH)D level on risk of diabetes [269]. Among participants treated with vitamin D (Fig. 76.9, upper panel), higher achieved intratrial blood 25(OH)D levels favorably influenced the risk of developing diabetes. In fully adjusted models, participants treated with vitamin D who maintained mean intratrial 25(OH)D levels of 40–49 and  $\geq 50$  ng/mL during follow-up were 52% and 71%, respectively, less likely to develop diabetes compared with those who maintained 25(OH)D levels of 20–29 ng/mL. In the placebo group (Fig. 76.9, lower panel), there was also a pattern of declining risk of diabetes at higher intratrial 25(OH)D levels, but the 95% CIs were wide.

Using the same methodology and individual participant data from the two vitamin D and diabetes prevention trials that administered cholecalciferol (D2d and Tromsø), participants treated with vitamin D who maintained intratrial 25(OH)D levels of 40–49 and  $\geq 50$  ng/mL during follow-up were 62% and 76%, respectively, less likely to develop diabetes compared with participants who maintained levels of 20–29 ng/mL [264]. Among participants assigned to placebo, the hazard ratios for diabetes were not significant by 25(OH)D category.

The dose–response findings in the D2d study and in the combined D2d/Tromsø studies that higher achieved 25(OH)D levels result in better treatment-related reductions in the incidence of diabetes increases the credibility

**FIGURE 76.9** Intra-trial cumulative blood 25(OH)D concentration and new-onset diabetes in the vitamin D and type 2 diabetes (D2d) study.

of the intention-to-treat analyses and strengthens the hypothesis that vitamin D plays a significant role in reducing risk of developing diabetes.

Although trials are expected to be free of confounding when they start because of randomization, biases may emerge during follow-up because of nonadherence to the trial intervention, use of rescue medications (e.g., metformin to prevent diabetes), or differential loss to follow-up. These biases, in turn, lead to postrandomization confounding, which may influence the true estimate of the effect of the intervention. Using the intratrial blood 25(OH)D level rather than the randomized assignment to assess the effect of vitamin D exposure on diabetes risk circumvents these sources of postrandomization confounding.

In total, these results indicate that avoiding vitamin D deficiency is desirable, and achieving higher blood 25(OH)D levels is needed to optimally reduce diabetes risk; the blood 25(OH)D threshold appears to be considerably higher than that recommended by the National Academy of Medicine for skeletal health, 20–29 ng/mL [268].

## 8. Effect modification of vitamin D supplementation by BMI

In the metaanalyses by Zhang et al. [257] and Barbarawi et al. [2], subgroup analyses showed that the benefit of vitamin D was primarily seen when combining data from trials with participants that had a mean baseline BMI in the nonobese category (<30 kg/m<sup>2</sup>) (27%

reduction in Zhang et al. and 32% reduction in Barbarawi et al.). Although these subgroup results in aggregate data metaanalyses are problematic, as noted earlier, the same result was reported in the metaanalysis by Pittas et al. using individual participant data [264]. When combining data from the three vitamin D and diabetes prevention trials, vitamin D (cholecalciferol or eldcalcitol) had a prominent effect among those with BMI <30 kg/m<sup>2</sup> (hazard ratio for vitamin D 0.79; 95% CI 0.66–0.95) while the effect was attenuated among those with BMI 30–34.9 kg/m<sup>2</sup> (hazard ratio 0.90; 95% confidence interval 0.72–1.12), and there was no effect among those with BMI ≥ 30 kg/m<sup>2</sup> (hazard ratio 1.07; 95% confidence interval 0.82–1.39).

This finding that the benefit of vitamin D may be more prominent in people with lower BMI while it is attenuated among those with higher BMI has been shown in other trials with vitamin D for nondiabetes outcomes. For example, in the VITAL study, subgroup analyses suggested differential effects of vitamin D on cancer incidence according to BMI, with normal-weight participants (BMI <25 kg/m<sup>2</sup>) who received cholecalciferol having a lower risk of developing cancer than those who received placebo compared with those with obesity (24% lower risk vs. 17% higher risk, respectively) [270]. Similar results were seen in the VITAL ancillary analyses on fractures. Participants with normal-weight (BMI <25 kg/m<sup>2</sup>) who received cholecalciferol had a lower rate of fractures than those who received placebo compared with those with obesity (7% lower risk vs. 17% higher risk, respectively) [271].

There are several possible explanations for the consistent finding that BMI, which reflects adiposity, modifies the vitamin D effect. Vitamin D is fat soluble, and increased sequestration in adipose tissue is thought to lead to decreased bioavailability in people who are obese [165], requiring a higher dose of vitamin D than patients with normal weight to achieve a similar increase in blood 25(OH)D concentration [110,112,272]. Beyond a “sequestration” effect or simply a “volumetric dilutional” effect, there is also evidence that obesity represses vitamin D bioactivation by CYP2R1 [113], leading to reduced production of 25(OH)D, and that weight loss upregulates CYP2R1 expression [114]. This explanation is supported by further results in the meta-analysis by Pittas et al. When individual participant data were combined from the two trials (Tromsø and D2d) that administered cholecalciferol, which requires activation to 25(OH)D in the liver and elsewhere by CYP2R1, there was a significant interaction by baseline BMI, so that supplementation with cholecalciferol reduced risk of diabetes in participants with a baseline BMI below the median of 31.3 kg/m<sup>2</sup> but less in those with BMI equal to or greater than the median (26% vs. 0%, respectively) [264]. In contrast, in the DPVD trial that used eldcalcitol, an active analog of vitamin D that does not require hydroxylation by CYP2R1 or CYP27B1, there was no effect modification by baseline BMI (*p* for interaction = 0.82) [6,264]. These results suggest that the effect of vitamin D on diabetes risk is mediated via its conversion to 25(OH)D by CYP2R1, which is primarily expressed in the liver but also in multiple other tissues including in pancreatic endocrine cells [115], and subsequently to 1.25(OH)<sub>2</sub>D by CYP27B1 in the kidney and pancreatic endocrine cells. This can explain why cholecalciferol appears to work better in leaner people with prediabetes and intact CYP2R1 bioactivity, but less well in those with overweight/obesity who are unable to fully convert vitamin D to 25(OH)D, thereby reducing the exposure of the beta-cell to the beneficial effects of the fully activated vitamin D molecule. Another explanation specific to the pathophysiology of type 2 diabetes is that a low BMI serves as a proxy for the predominance of a pancreatic beta-cell defect (insulin deficiency) in people with prediabetes who benefit the most with vitamin D, since a key proposed mechanism of vitamin D is improvement in insulin secretion. This explanation is supported by results from the DPVD study, which showed that the benefit of eldcalcitol in reducing risk of diabetes was most apparent in participants with insulin secretion at baseline (hazard ratio for vitamin D 0.41; 95% confidence interval 0.23–0.71).

Finally, pancreatic  $\beta$ -cell autoimmunity, which may be present in more than 10% of people diagnosed with type 2 diabetes, leading to pancreatic  $\beta$ -cell destruction is a pathway towards insulin deficiency among non-

obese people, and high-dose vitamin D may attenuate the autoimmune-mediated pathology. Testing the hypothesis that vitamin D helped predominantly participants with prediabetes and evidence of  $\beta$ -cell autoimmunity would be a compelling area for future research to better identify populations at risk for diabetes that are most likely to benefit from vitamin D.

## 9. Safety of vitamin D supplementation for prevention of type 2 diabetes

When examining the benefit of vitamin D for prevention of type 2 diabetes, potential safety concerns need to be addressed. In each of the three vitamin D and type 2 diabetes prevention trials, protocol-specified adverse events of interest (hypercalcemia, hypercalciuria, nephrolithiasis) were rare, and there were no differences between the vitamin D and placebo groups [4–6]. Detailed data from the D2d study support the safety of cholecalciferol 4000 IU per day in overweight/obese participants at high risk for diabetes who were appropriately monitored for safety. Overall, a total of 8304 adverse events occurred during 3 years of follow-up and were less frequent in the vitamin D group compared with placebo (incidence rate ratio 0.94; 95% CI 0.90, 0.98). The overall frequency of protocol-specified adverse events of interest, which included nephrolithiasis, hypercalcemia, hypercalciuria, or low estimated glomerular filtration rate, was low and did not differ by group. There were no significant between-group differences in total serious adverse events. The metaanalysis by Pittas et al. that combined individual participant data from the three large randomized, placebo-controlled trials of vitamin D—only supplementation among adults with prediabetes also assessed safety [264]. During a median follow-up of 3.0 years, the incidence of kidney stones, hypercalcemia, hypercalciuria, and death from any cause did not differ between the groups.

## 10. Conclusions

Results from longitudinal observational studies provide strong support of an association between vitamin D status and development of type 2 diabetes, supported by biological plausibility raising the possibility that optimizing vitamin D status has role when caring for patients with or at risk for type 2 diabetes. The results from mostly underpowered trials and *post hoc* analyses of large trials that used small doses of vitamin D do not support a role of vitamin D for treatment of established type 2 diabetes or prevention of diabetes among those with normal glucose tolerance. In people with prediabetes, vitamin D reduces risk of progression to diabetes and promotes

regression to normal glucose regulation. For optimal risk reduction, blood 25(OH) levels higher than those recommended by the National Academy of Medicine are needed.

## 11. Summary points

- Vitamin D plays a role in pancreatic beta-cell function, insulin action, and systemic inflammation providing mechanistic links between vitamin D and risk of type 2 diabetes.
- Conventional longitudinal observational studies report highly consistent inverse associations between blood 25(OH)D concentration and risk of developing type 2 diabetes. However, confounding is a key limitation.
- Mendelian randomization studies do not support linear associations between genetically determined blood 25(OH)D levels and risk of type 2 diabetes; however, Mendelian randomization studies center upon assumptions that are not relevant to vitamin D physiology.
- In people with normal glucose tolerance or those at average risk for type 2 diabetes, there is no evidence that vitamin D improves glucose tolerance or reduces risk of developing diabetes.
- In people at risk for type 2 diabetes (prediabetes), vitamin D reduces risk of progression from prediabetes to diabetes.
- In people at risk for type 2 diabetes (prediabetes), vitamin D promotes regression to normal glucose regulation.
- For optimal glycemic outcomes in people at risk for type 2 diabetes, blood 25(OH) levels higher than those recommended by the National Academy of Medicine are needed.
- The effect of vitamin D on prevention of type 2 diabetes is attenuated in those with overweight or obesity. Higher doses of cholecalciferol or the use of activated metabolites may be needed for adults with obesity.
- At doses given in the diabetes prevention trials in people with prediabetes, vitamin D is safe.

# Liver metabolism and disease

*Bingning Dong*

Baylor College of Medicine Houston, Houston, TX, United States

## OBJECTIVES

Vitamin D is well known for its role in calcium and skeletal homeostasis, and it exerts pleiotropic biological functions.  $1\alpha,25$ -Dihydroxyvitamin D<sub>3</sub> ( $1,25(\text{OH})_2\text{D}$ ), the active form of vitamin D derived from  $1\alpha$ -hydroxylation of 25-hydroxyvitamin D ( $25(\text{OH})\text{D}$ ), mediates its function mainly through binding to D receptor (VDR). The  $1,25(\text{OH})_2\text{D}$ –VDR complex regulates its target genes expression by binding to vitamin D response elements (VDREs) in target genes. In the liver, VDR is expressed highly in nonparenchymal cells, including KCs (Kupffer cells), HSCs (hepatic stellate cells), and cholangiocytes, whereas in the hepatocytes, its expression is relatively low.  $1,25(\text{OH})_2\text{D}$ –VDR signaling has been reported to inhibit liver inflammation and fibrosis and antiproliferative effects. Altered  $1,25(\text{OH})_2\text{D}$ –VDR signaling is commonly related with the occurrence, natural course, and outcome of chronic liver diseases. In this chapter, we will mainly discuss the role of  $1,25(\text{OH})_2\text{D}$  and VDR signaling in liver inflammation, fibrosis, and nonalcoholic steatohepatitis (NASH).

## 1. Introduction

The liver is renowned for its essential roles in preserving and regulating the levels of lipid and glucose in the body and energy metabolism. Hepatocytes are responsible for disparate metabolic tasks of energy storage and supply. Hepatic steatosis results from the imbalance between hepatic lipid supply and

utilization [1–3]. Nonalcoholic fatty liver disease (NAFLD) is defined as the accumulation of lipids in the liver in the absence of secondary causes, such as excess alcohol consumption and other chronic liver diseases. NAFLD is a complex liver disease with conditions varying in hepatic lipid deposition, inflammation, hepatocytes injury, and the associated fibrosis. Among these, simple hepatic steatosis (fatty liver) is referred to as NAFL, and nonalcoholic steatohepatitis (NASH) is defined as a more aggressive condition with inflammation and fibrosis. NASH may progress to adverse hepatic outcomes, including cirrhosis, liver failure, and hepatocellular carcinoma (HCC) [4]. NAFLD is strongly associated with obesity and type 2 diabetes mellitus (T2DM) and has become the most common cause of chronic liver disease with a worldwide prevalence of 25%. In the United States, the number of NAFLD cases is projected to expand from 83.1 million in 2015 to 100.9 million in 2030 [5]. The more aggressive NASH will rise from 20% to 27% of adults in these NAFLD cases. As NAFLD/NASH progresses, hepatic inflammation and fibrosis develop, which increases the risk of severe systematic liver diseases, including cirrhosis and HCC [6,7]. This rising liver metabolism-associated disease prevalence will exact a growing economic burden on patients with cirrhosis and end-stage liver disease, including HCC requiring liver transplantation. Over the past decades, great effort has been dedicated to understanding the mechanisms of NAFLD pathogenesis; however, identifying therapeutic targets and advancing drug development are still significant unmet challenges, and no agent is available yet for NAFLD or NASH. Therefore, identifying predictive biomarkers of disease risk, key pathogenic drivers, and novel therapeutic targets are urgently needed.

The liver has several routes of lipid acquisition: On one hand, enhanced lipid uptake resulting from white adipose tissue (WAT) insulin resistance induces circulating fatty acid (FA) flux to the liver with subsequent ectopic hepatic lipid deposition. On the other hand, hepatic insulin resistance and excess dietary fructose drive *de novo* lipid synthesis (DNL). It is estimated that dysregulated hepatic lipid uptake accounts for more than half of fatty liver in NAFLD patients [8]. Several free fatty acid transporters, including CD36, fatty acid transport protein 2 (FATP2), and FATP5, have been identified for their function in liver lipid uptake. Hepatocyte-specific ablation of CD36 ameliorates high-fat diet (HFD)–induced NAFLD in mice [9], whereas ablation or knockdown of liver FATP2 or FATP5 alleviates liver steatosis [10,11]. Several nuclear receptors, including peroxisome proliferator–activated receptor- $\gamma$  (PPAR $\gamma$ ), pregnane X receptor (PXR), TAK1/TR4, and aryl hydrocarbon receptor (AHR), directly upregulate CD36 expression and promote liver steatosis [12–15]. PPAR $\gamma$  also promotes hepatic lipid storage by inducing the expression of lipid droplet proteins, whereas hepatocyte-specific deletion of PPAR $\gamma$  decreases HFD-induced hepatic steatosis [16,17]. Hepatic lipid uptake correlates with the release of free fatty acids (FFAs) from white adipose tissue, facilitating lipid trafficking from adipose tissue to the liver during the course of NAFLD pathogenesis [18]. In addition to circulating fatty acids, endoplasmic reticulum (ER) stress–induced hepatic very-low-density lipoprotein receptor (VLDLR) protein expression leads to hepatic steatosis by increasing lipoprotein delivery to the liver [19]. Hepatic *de novo* lipogenesis (DNL) contributes to about 11%, 19%, and 38% of intrahepatic triglyceride (TAG) in the lean, obese, and obese-NAFLD humans, respectively [20]. Dietary sugars, including glucose and fructose, are potent inducers of hepatic lipid synthesis and contribute to NAFLD progression (52, 138). Glucose is metabolized into fatty acids through a chain of reactions mediated by glycolysis, glucose oxidation (TCA cycle), and fatty acid synthesis enzymes. Subsequently, the long-chain fatty acids (LCFAs) are activated to generate LCFA-CoA, providing substrates for triacylglycerol (TAG) synthesis.

The mechanism(s) responsible for increasing hepatic DNL in individuals with NAFLD is not completely understood. Although glucose metabolism is dysregulated with whole-body insulin resistance, hepatic DNL is induced by elevated insulin through activating two master DNL genes, including the sterol regulatory element–binding protein 1c (SREBP-1c) and carbohydrate response element–binding protein (ChREBP), and by the lipogenic transcription factor liver X receptor (LXR) [21–23]. This phenomenon implies differential insulin actions during insulin resistance—suppressing

hepatic glucose production but preserving insulin sensitivity with respect to the SREBP-1c pathway that stimulates fatty acid synthesis. This differential regulation could be at least partially explained by the activation of mTORC1 signaling by excess insulin, which regulates SREBP1c mRNA expression and processing [24,25]. SREBP1c is also regulated independently of insulin, as demonstrated by induction of SREBP1c after feeding in the liver-specific insulin receptor knockout mice [26]. Pharmacological inhibition of DNL, for example, using acetyl-CoA carboxylase inhibitors (MK-4074 and PF-05221304), decreases liver steatosis in patients with NAFLD [27]. Recently, overconsumption of food containing high-sugar/high-fructose corn syrup was linked to NAFLD and NASH development in humans. While the glucose-induced DNL pathway is highly regulated, nearly all fructose is metabolized and committed to DNL by the liver and cleared from portal blood. In the liver, fructose is phosphorylated by ketohexokinase to form fructose-1-phosphate (F1P). F1P then generates substrates for DNL and serves as an allosteric activator of glucokinase, which enhances glycolytic flux in hepatocytes [28]. A large fructose load results in the depletion of liver ATP in humans and animals, which may enhance cellular stress and hepatic damage, leading to NASH development [29].

Several epidemiological studies have reported the correlation of vitamin D deficiency (low serum 25(OH)D) or low 25(OH)D with NAFLD and provided evidence that these conditions increased disease risk. Notably, low serum 25(OH)D levels correlate with the severity of steatosis and hepatic inflammation-related damage. Indeed, vitamin D deficiency is very common in people with NAFLD and NASH [30–32]. For example, a meta-analysis of 29 case–control and cross-sectional studies found that NAFLD patients had significantly lower levels of 25(OH)D and were 1.26 times more likely to be vitamin D deficient. NASH patients also had significantly lower levels of 25(OH)D [30]. A recent Korean cohort study also supported that serum vitamin D level is inversely correlated with NAFLD [33]. Although clinical and metaanalysis studies suggest an inverse association between 25(OH)D and the histologic and pathologic severity of NAFLD and NASH, a clear causal nexus between vitamin D signaling and liver diseases is not determined. Besides, there are also conflicting reports suggesting a lack of association between vitamin D levels and NAFLD severity [34] and no efficacy of vitamin D supplementation on NAFLD treatment [35]. Similar contradictory results also show no association between serum vitamin D levels and vitamin D supplement efficacy in T2DM [36].

The steroid hormone form of vitamin D, 1,25(OH) $_2$ D, is best known for its role in calcium and skeletal homeostasis but is also recognized for its nonskeletal functions

**FIGURE 77.1 Schematic representation of vitamin D/VDR signaling on chronic liver diseases.** Vitamin D is obtained mainly through diet sources (oily fish, meat, milk, and others) and supplements. Sunlight exposure is a natural source of vitamin D synthesis. Vitamin D becomes activated in the liver and kidney and then mediates its function mainly through binding to its receptor VDR. VDR is highly expressed in the nonparenchymal hepatocytes including the hepatic macrophages and stellate cells. Activated VDR heterodimerizes with the cofactor RXR. The VDR/RXR complex translocates to the nucleus, binds to its specific genomic sequences (VDREs) in the promoter region, and regulates the transcription of target genes. In Kupffer cells and hepatic macrophages, VDR signaling interferes with NF-κB signaling and inhibits the expression of TLRs to reduce inflammation. On the other hand, VDR signaling results in reduced HSC proliferation through inhibiting TGFβ/Smad signaling, thus contributing to the alleviation of liver fibrosis. Inflammation and fibrosis are hallmarks of disease progression from NAFLD to NASH and NASH-HCC. Therefore, activation of VDR signaling is a promising intervention for obesity-associated chronic liver diseases.

in immunity, inflammation, cell proliferation, and differentiation [37,38] (see **Volume 2** of this book). The biological functions of  $1,25(\text{OH})_2\text{D}$  are primarily mediated through binding to VDR, a member of the nuclear receptor superfamily (see Chapters 10–13). In the healthy liver, VDR is expressed highly in nonparenchymal cells, including Kupffer cells (KCs), hepatic stellate cells (HSCs), and cholangiocytes. In contrast, the remaining epithelial and resident immune cells express relatively low levels of VDR. Several reports have shown that  $1,25(\text{OH})_2\text{D}$  binding to VDR exerts an inhibitory effect on liver inflammation and fibrosis [39–41]. This chapter will focus mainly on the actions of VDR in hepatic immune cells and stellate cells in NAFLD and NASH (Fig. 101.1).

## 2. Vitamin D/VDR signaling and antiinflammatory responses in the liver

Vitamin D signaling has been well studied for its nonskeletal functions in regulating immunity, inflammation, proliferation, and differentiation [37,38] (see Chapters 94–96). In particular, as part of its antiinflammatory, VDR interacts with IKKβ to interrupt nuclear factor-κB (NF-κB) signaling [42,43]. VDR signaling also reduces Toll-like receptor (TLR)–mediated inflammation in hepatic macrophages and suppresses TLR4-mediated inflammation [44]. At least part of the VDR

antiinflammatory effect is mediated through downregulating miR-155, which derepresses SOCS1, leading to heightened negative feedback regulatory action [45]. As a master regulator of inflammation, NF-κB plays a critical role in the expression of proinflammatory cytokines, such as interleukin (IL)-1β and IL-6. Inactivation of NF-κB signaling protects mice from obesity-induced insulin resistance [46–48]. Thus, VDR activation may improve insulin resistance and T2D through antiinflammatory suppression of NF-κB signaling. Vitamin D–mediated VDR activation promotes macrophage differentiation in vitro and suppresses cytokine secretion in T2D [49]. Deletion of macrophage VDR induces insulin resistance and promotes monocyte cholesterol transport to accelerate atherosclerosis in mice [50]. Suppression of NF-κB activity is the main mechanism for the antiinflammatory function of VDR signaling in hepatic macrophages. Under the NAFLD/NASH condition, liver KCs and the recruited macrophages cross-talk with hepatocytes to regulate inflammation. Hepatic NF-κB activity regulates insulin sensitivity in obesity condition. IKKβ, the key component in the NF-κB cascade, was reported to inhibit insulin sensitivity by inducing IL-1β or IL-6 expression [46,48,51]. We reported that the VDR analog (calcipotriol) suppresses IL-1β, IL-6, and P65 expression in the HFD-induced mouse fatty liver [41]. This supports that VDR activation suppresses liver inflammation to regulate insulin sensitivity and diabetes. Wei et al. reported that VDR regulates β-cell inflammation and sur-

vival through switching the SWI/SNF (BAF) chromatin remodeling complexes [52]. Inhibition of the interaction of VDR-BRD9 (bromodomain-containing proteins) combined with activation of VDR signaling cooperate to dismiss the BAF-BRD9 complex and shift the balance to the activating PBAF-BRD7 complex form to induce a coordinated transcriptional response. Pharmacological activation of VDR signaling by calcipotriol in combination with a BRD9 inhibitor was able to partially restore  $\beta$ -cell function and glucose homeostasis in T2D mouse models. As a consequence, NAFLD condition is also ameliorated [52]. Endoplasmic reticulum (ER) stress occurs when ER homeostasis is disturbed with accumulation of unfolded/misfolded protein or calcium depletion. Under pathological condition, ER stress is associated with liver inflammation, fatty liver development, and fibrosis [53,54]. The antiinflammatory functions of macrophage VDR signaling have also been described in the context of hepatic ER stress resolution in normal chow and HFD-fed mice. Specifically, VDR activation suppresses chemical and diet-induced hepatic ER stress response; VDR knockout mice exhibited persistent unfolded protein response, resulting in hepatic cell death and inflammation and progression of liver disease [55]. In line with this, vitamin D supplementation can improve chronic low-grade inflammation and diabetic condition in T2D patients [56–58]. Therefore, targeting VDR signaling highlights a great potential in ameliorating chronic metabolic diseases. Recently, in a randomized, double-blind, placebo-controlled trial ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT04038853) NCT04038853) found that low-to medium-dose vitamin D supplementation (1000 IU/day) over 12 months reduces the transient elastography indices of liver steatosis and fibrosis in unselected adult patients with NAFLD [59]. In another study, treatment with 2100 IU vitamin D daily over 48 weeks showed a significant improvement of serum ALT levels in patients with hypovitaminosis D and histology-proven NASH. As for NAFLD, primary endpoint showed a trend toward reduction of hepatic steatosis, however, not significant due to a small number of available biopsy specimens [60].

### 3. Vitamin D/VDR signaling in liver fibrosis and NASH

In regard to chronic liver diseases, including liver fibrosis and NASH, HSCs are the major effector cells in the pathogenic wound healing process, leading to liver fibrosis. HSCs provide the predominant source of hepatic extracellular matrix. VDR is highly expressed in HSCs, albeit at lower levels than KCs. VDR activation by 1,25(OH)<sub>2</sub>D in HSCs strongly antagonizes TGF $\beta$  signaling, the most potent profibrogenic pathway in

the liver. This leads to the suppression of a broad range of profibrotic genes, including collagens, integrins, and tissue inhibitors of metalloproteinase [61,62]. Moreover, mouse model studies reveal that spontaneous liver fibrosis occurs when one or both *Vdr* alleles are knocked out, with more severe fibrosis observed in the *Vdr* null mice. More importantly, vitamin D administration resulted in decreased VDR degradation and attenuation of TGF $\beta$ 1-induced fibrosis. Ding et al. demonstrated a genomic circuit between VDR and SMAD to compete TGF $\beta$  signaling. Interestingly, SMAD-mediated TGF $\beta$  signaling enhanced the accessibility of ligand-bound VDR with these genomic loci, which in turn antagonized the recruitment of SMAD3 [62]. Another study addressed the amelioration of hepatic inflammation, fibrosis, and HCC in HSCs through *P62* binding to VDR, which promotes VDR signaling in HSCs and facilitates the stabilization of the VDR/RXR heterodimer [63]. Therefore, it is of note that *P62* levels should be monitored when designing clinical approaches involving targeting VDR in liver fibrosis, NASH, and associated HCC. Given recent data revealing the importance of activated myofibroblasts to NASH and tumor promotion, it is of great interest to investigate detailed mechanisms and the potential of clinical usage of HSC VDR actions during NASH and associated HCC development.

Targeting VDR signaling opens a novel therapeutic window for NAFLD, NASH, and NASH-associated HCC. However, conflicting results from different clinical cohorts puzzled the development of VDR-targeted intervention. One caveat comes from the different forms of vitamin D and its synthetic analogs used in different studies and their various efficacy in activating VDR. The other challenge is the side effect of VDR ligands in elevating serum calcium levels (hypercalcemia). Until now, “noncalcemic” VDR ligands are still in development. Specifically, Dong et al. utilized low-dose calcipotriol administration to achieve therapeutic efficacy in the HFD-induced obesity mouse model without inducing elevated serum calcium level or toxicity [41]. Hepatic macrophages are an attractive target for novel therapies to treat liver steatosis and insulin resistance. KCs and monocytes-derived macrophages have high scavenging capacity, highlighting the potential for precise drug delivery. Evidence from mouse models and human clinical studies supports the notion that the pathogenic macrophage subsets can be successfully targeted under the NASH and liver fibrosis conditions, supporting novel treatment avenues in the future. Clinically relevant carrier materials such as microbubbles, liposomes, and polymers can be detected in the liver, and KCs are the main cellular target for these materials [64]. Dexamethasone coupled with mannosylated albumin can selectively deliver antiinflammatory drugs to the KC,

reducing intrahepatic reactive oxygen species (ROS), inflammation, and fibrosis [65,66]. Besides, emerging fields of medical applications such as nanomedicine may hold exceptional potential for novel therapeutic approaches targeting liver macrophages in liver disease [67,68]. Therefore, the current controversial therapeutic effect of vitamin D in NAFLD might be greatly improved by novel drug carrier materials delivering 1,25(OH)<sub>2</sub>D or its synthetic analogs to the hepatic macrophages to control liver inflammation, NAFLD, and NASH. Targeted delivery of therapeutics to the activated HSCs is critical for successfully treating chronic liver diseases. Many fibrogenic markers, such as type VI collagen receptor, RBP receptor, PDGFR $\beta$ , synaptophysin, IGFIR, LDLR, and CD44, have been identified for activated HSCs [69]. Their ligands have been used to specifically deliver various antifibrotic agents. Despite great efforts in developing targeted delivery systems for liver fibrosis in preclinical studies, precise targeted drug delivery has not been successful in clinical trials. Among clinical trials testing small molecules, proteins, monoclonal antibodies, and nucleic acids in liver fibrosis, one clinical trial (NCT02227459) has used vitamin A as a targeting ligand. Vitamin A-based nanoparticle delivery can successfully deliver antifibrotic siRNAs, miRNAs, or drugs into activated HSCs and reduce the expression of profibrotic genes. Hepatic fibrosis is a consequence of the accumulation of inflammatory cytokines and numerous ECM proteins in the damaged liver. Therefore, targeting one protein expression via gene silencing may not produce efficient results, which is one of the main limitations of siRNA-based therapeutics. However, with combined vitamin D treatment, the activated VDR signaling may provide promising therapeutic effects in the future NAFLD and NASH treatments.

#### 4. Conclusions

Vitamin D is a molecule exerting beneficial effects at several sites of biological homeostasis, besides its central role in bone and mineral homeostasis. Extensive research over the past decades has pointed 1,25(OH)<sub>2</sub>D as a key player in the regulation of liver inflammation and fibrosis. Vitamin D–VDR axis modulates signaling pathways that control antiproliferative, antiinflammatory, and antifibrotic functions in VDR expressing cell types in the liver. In support, the epidemiological evidence of an association between hypovitamin D and the presence of NAFLD and NASH reinforces the rationale of aiming to restore optimal vitamin D levels as a therapeutic intervention for the management of NAFLD and NASH. The measurement of blood 25(OH)D concentration allows personalization

of the supplementation regimen and monitoring of the safety of the treatment throughout the treatment period. Currently, the overall number of randomized clinical trials investigating the effects of vitamin D supplementation in NAFLD and NASH is very limited. Due to high risk of bias and insufficient power of the included trials, further investigations with appropriate study design may be needed to define the benefit of effect of vitamin D supplement on the NAFLD and NASH.

#### 5. Summary points

- Vitamin D by binding to VDR modulates signaling pathways involving antiproliferative, antiinflammatory, and antifibrotic functions in liver nonparenchymal cells.
- Vitamin D deficiency associates with the incidence of NAFLD and NASH in patients.
- Vitamin D/VDR signaling shows beneficial effects in the treatment of NAFLD and NASH in mouse models and some clinical human studies.
- Further clinical investigations with appropriate study design are required to draw the conclusion of whether vitamin D supplementation can serve as an effective intervention in NAFLD and NASH.

# Vitamin D, hypertension, and cardiovascular disease\*

Armin Zittermann<sup>1</sup> and Stefan Pilz<sup>2</sup>

<sup>1</sup>Clinic for Thoracic and Cardiovascular Surgery, Herz- und Diabeteszentrum NRW, Ruhr, University Bochum, Bad Oeynhausen, Germany <sup>2</sup>Department of Internal Medicine, Division of Endocrinology and Diabetology, Medical, University of Graz, Graz, Austria

## OBJECTIVES

- It has long been known that supraphysiological vitamin D doses cause vascular calcification. More recently, evidence has accumulated that vitamin D may also exert beneficial effects on the cardiovascular system. Therefore, the potential link between vitamin D deficiency and CVD risk has been rigorously studied.
- Since CVD is a leading cause of morbidity and mortality globally, and an inadequate vitamin D status is a worldwide issue as well, the preventive role of vitamin D with regard to the risk of CVD will be the focus of this chapter.
- Several lines of evidence regarding vitamin D and CVD will be summarized. Available data come from experimental animals, patients with rickets or osteomalacia, large prospective cohort studies, genetic association studies, and randomized controlled trials.
- Since harmful vitamin D effects on the cardiovascular system are an issue as well, potential benefits of vitamin D will be weighted against potential harm.

- Finally, conclusions are drawn regarding the practical consequences of the results.

## 1. Introduction

About a hundred years ago, it was discovered that rickets, a disease involving inadequate mineralization of the growing skeleton, and which was endemic in children in North America and Europe at that time, was mainly caused by vitamin D deficiency [1]. The rapid establishment of vitamin D prevention measures could effectively erase this endemic. However, both experimental animal studies and data in children also soon showed that those vitamin D doses, which are now considered supraphysiological, can lead to massive calcification of soft tissues such as vessels and kidneys [2,3]. For this reason, the adverse effects of vitamin D on the cardiovascular system have long been the focus of interest [4–6], and it had been suggested that damage of the cardiovascular system by high doses of vitamin D may predispose for atherosclerosis [4,6]. In line with this assumption, the approach of high-dose intermittent administration of vitamin D for the prevention of rickets

\* **Short note:** Meanwhile, the statistical approach of the two non-linear Mendelian randomization studies mentioned in this chapter [68,77] has been questioned [Smith GD. *Lancet Diabetes Endocrinol.* 2023;11:14]. Indeed, a recalculation of the data by the lead authors of one of the two articles revealed a null effect instead of an increased CVD risk at deficient 25(OH)D levels [Burgess et al. *Lancet Diabetes Endocrinol.* 2023;11:15–6]. Consequently, there is currently no good evidence that even deficient circulating 25(OH)D concentrations increase the risk of CVD.

(six doses of 600,000 IU vitamin D<sub>2</sub> divided over the first 1.5 years of life), which was performed for decades, especially in parts of Germany, led to very high 25-hydroxyvitamin D (25(OH)D) concentrations in the circulation (several hundred and up to more than one thousand nmol/L) and, in one-third of the cases studied, also to hypercalcemia [7]. This strategy of rickets prevention has also been associated with premature death in some children [8].

In the early 1980s, Robert Scragg, taking ecological data as his basis, was one of the first to focus on the association of vitamin D deficiency with cardiovascular disease (CVD). He suggested that vitamin D deficiency may contribute to the risk of CVD [9]. His assumption was based on (1) the circannual rhythm in cardiovascular mortality with a peak in winter and a nadir in summer, (2) the fact that these fluctuations cannot be adequately explained by suggested risk factors such as temperature or respiratory infections, and (3) seasonal variations in solar ultraviolet B radiation, and thus human vitamin D status, parallel the observed CVD findings. The vitamin D deficiency hypothesis is also in agreement with differences in CVD risk by geographic latitude, altitude, and place of residence (rural or urban) [10].

Altogether, the aforementioned data indicate a biphasic vitamin D effect on the cardiovascular system with detrimental consequences from both deficiency and intoxication.

During the past decades, the effects of vitamin D on the cardiovascular system and CVD outcomes have been rigorously studied. CVD includes various illnesses, among them hypertension, heart failure, myocardial infarction, and stroke. Several lines of evidence regarding vitamin D and CVD are now available, such as knockout models in experimental animals, large prospective cohort studies, genetic association studies, and randomized controlled trials (RCTs). Since CVD is a leading cause of morbidity and mortality globally, and an inadequate vitamin D status is a worldwide issue as well, the preventive role of vitamin D with regard to the risk of CVD has been the focus of these recent studies and is also the focus of this article.

## 2. Vitamin D metabolism and regulation with special reference to cardiovascular disease

Circulating 25(OH)D is the generally accepted indicator of human vitamin D status. 25(OH)D is produced in the liver from cutaneously synthesized or orally ingested vitamin D. After hepatic hydroxylation, 25(OH)D is rapidly released into the circulation. According to the Institute of Medicine [11], values < 30 nmol/L are classified as deficient, between 30 and 50 nmol/L as inadequate, between 50 and 125 nmol/L as adequate, and

>125 nmol/L as potentially harmful. For adults, the Institute of Medicine considers daily vitamin D doses of 600–800 as adequate, and the upper tolerable intake level has been set at 4000 IU daily [11]. Nevertheless, there is an ongoing debate about the classification of vitamin D status according to circulating 25(OH)D, and an Endocrine Society recommendation considers a concentration of 75 nmol/L as target value and values up to 250 nmol/L as safe [12]. The corresponding recommended daily intake of the Endocrine Society is 1500–2000 IU, and the safe upper intake level is set at 10,000 IU.

Besides this ongoing discussion, the use of circulating 25(OH)D as an indicator for vitamin D status is also complicated by the fact that 25(OH)D is only the precursor of the active hormone, 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D), which is synthesized primarily in the kidney, but also in extrarenal tissues. Renal synthesis of 1,25(OH)<sub>2</sub>D is usually tightly regulated by parathyroid hormone (PTH) and fibroblast growth factor-23 (FGF23) to maintain plasma calcium and phosphate within their relatively narrow physiological ranges (see Chapter 8). FGF23 binds to its cell surface receptor with much higher affinity in the presence of a cofactor, called klotho. FGF23 inhibits 1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase or CYP27B1) and activates 24-hydroxylase (24-OHase or CYP24A1) (see Chapter 19), resulting in decreased 1,25(OH)<sub>2</sub>D and increased 24,25(OH)<sub>2</sub>D levels [13], whereas 1 $\alpha$ -OHase is activated by PTH, as a consequence of low plasma calcium levels [14] (see Chapter 17). At circulating 25(OH)D concentration <30 nmol/L, however, renal 1,25(OH)<sub>2</sub>D synthesis becomes also substrate-dependent. Consequently, deficient vitamin D (serum 25(OH)D) status is often associated with low circulating 1,25(OH)<sub>2</sub>D concentrations and secondary hyperparathyroidism (reference range of PTH: 10–60 pg/mL), while PTH is only slightly elevated and 1,25(OH)<sub>2</sub>D only slightly decreased (but may also be normal or relatively high) at circulating 25(OH)D between 30 and 50 nmol/L [15].

PTH excess is linked to endothelial dysfunction [16] and arterial hypertension [17]. In chronic kidney disease (CKD), secondary hyperparathyroidism and elevated phosphate levels seem to contribute to the high prevalence of vascular calcification and CVD [18] (see Chapter 79). With respect to FGF23, extremely high (several thousand research units (RU)/mL; reference range: <100 RU/mL) concentrations have been described in diseases with low circulating 1,25(OH)<sub>2</sub>D concentrations, such as chronic kidney disease and end-stage heart failure [19–21]. There is evidence that FGF23 activates the renin–angiotensin–aldosterone system (RAAS) and leads to cardiac left ventricular hypertrophy by a calcineurin- and nuclear factor of activated T cells (NFAT)–mediated process [22,23]. Thus, FGF23 is a good predictor of heart failure outcome [24,25]. FGF23 is also a good

predictor of cardiovascular and all-cause mortality [26,27], with a gradual and progressive rise in the risk of all-cause mortality as FGF23 increases [27] (see Chapter 19).

### 3. Vitamin D effects on cardiovascular cells

There is growing evidence that vitamin D signaling has important functions in endothelial cells, vascular smooth muscle cells (VSMC), and cardiomyocytes [28]. The effects of vitamin D in cardiovascular cells are based on its active hormone,  $1,25(\text{OH})_2\text{D}$ , which is either incorporated from the circulation via a membrane-bound vitamin D receptor (VDR) or formed from its precursor  $25(\text{OH})\text{D}$  by an intracellular  $1\alpha\text{-OHase}$  [29]. Thus, it appears likely that  $1,25(\text{OH})_2\text{D}$  can act in an endocrine, autocrine, and paracrine fashion on the cardiovascular system. The effects of  $1,25(\text{OH})_2\text{D}$  are mediated by non-genomic and genomic actions, thereby regulating intracellular calcium metabolism by the rapid release of ionized calcium from intracellular stores or by calcium-binding protein (CaBP) synthesis [28]. Similar to the control of circulating  $1,25(\text{OH})_2\text{D}$ , the synthesis of  $1,25(\text{OH})_2\text{D}$  in the heart and the vasculature seems to be regulated by PTH and FGF23 [30,31].

The effects of  $1,25(\text{OH})_2\text{D}$  on the vascular system appear to be a double-edged sword: several beneficial effects such as a reduction in thrombogenicity, a decrease in vasoconstrictors, an inhibition of oxidative stress and atherogenesis, an improvement in endothelial repair, a reduction in foam cell formation, and vascular relaxation and dilatation have been reported [32,33]. In addition, a lack of  $1,25(\text{OH})_2\text{D}$  promotes transdifferentiation of VSMCs into osteoblast-like cells by suppression of IL-4, IL-10, Matrix-gla protein, osteopontin, osteoprotegerin, and fetuin A and may thus lead to vascular calcification [34].  $1,25(\text{OH})_2\text{D}$  is also considered to be a negative endocrine regulator of the RAAS [35], whose activation plays a pivotal role in hypertension and other CVDs. A lack of vitamin D action by selective deletion of vitamin D receptors (VDR) in endothelial cells increases the sensitivity of the vascular wall to angiotensin II, thereby increasing systemic blood pressure [32]. However, elevated circulating  $1,25(\text{OH})_2\text{D}$  may also contribute to essential hypertension by facilitating calcium transport from the extracellular space into the cell [36], leading to increased smooth muscle cell contractility. In addition, elevated  $1,25(\text{OH})_2\text{D}$  concentrations can promote vascular calcification either by direct hypercalcemic (plasma calcium  $>2.6$  mmol/L) and hyperphosphatemic (plasma phosphate  $>1.61$  mmol/L) effects or by transdifferentiation of VSMCs into osteoblast-like cells [34,37]. In line with this, children on dialysis show a

U-shaped distribution of carotid intima-media thickness and calcification scores across circulating  $1,25(\text{OH})_2\text{D}$  levels: patients with both low and high  $1,25(\text{OH})_2\text{D}$  concentrations in the circulation have significantly greater carotid intima-media thickness and calcification than those with normal levels [38]. The potentially adverse effects of  $1,25(\text{OH})_2\text{D}$  on the cardiovascular system are also underlined by findings that vascular calcification is mediated by an increase in  $1\alpha\text{-hydroxylase}$  expression in VSMCs [39], and loss-of-function mutations of either FGF23 or klotho can induce ectopic calcification [40,41].

### 4. Vitamin D effects in experimental animals

Various rodent models have been used to study the effect of vitamin D on the cardiovascular system in vivo. The models include feeding diets with deficient or excess vitamin D content, generating uremic animals with low circulating  $1,25(\text{OH})_2\text{D}$  concentrations, disrupting vitamin D pathways by deletion of (1) the *Cyp27b1* gene encoding for the  $1\alpha\text{-OHase}$ , (2) the global *Vdr*, or (3) the cardiomyocyte-specific *Vdr*, and generating animals with  $1,25(\text{OH})_2\text{D}$  overexpression.

In normal mice, vitamin D deficiency stimulates renin synthesis, whereas the injection of  $1,25(\text{OH})_2\text{D}$  reduces renin synthesis [35]. Diets with deficient vitamin D content also stimulate osteoblast-like cell formation of VSMCs and aortic calcification in experimental mice [42,43]. In experimental uremia, secondary hyperparathyroidism and hyperphosphatemia are associated with vascular calcification [44]. In  $1\alpha\text{-OHase}$  (*Cyp27b1*) knockout mice, administration of  $1,25(\text{OH})_2\text{D}$  can prevent an upregulation of the RAAS in renal and cardiac tissue and the development of hypertension, cardiac hypertrophy, and impaired cardiac function. These vitamin D effects are independent of plasma calcium and phosphate concentrations [45].

Deletion of the gene for VDR (*Vdr*) in mice has also been reported to elevate production of renin and angiotensin II, leading to hypertension and cardiac hypertrophy [46,47]. Moreover, treatment of VDR knockout mice with the angiotensin-converting enzyme inhibitor captopril reduced cardiac hypertrophy and normalized atrial natriuretic peptide expression [47]. Cardiomyocyte-specific deletion of the VDR resulted in cardiac hypertrophy as well, and treatment of neonatal cardiomyocytes with  $1,25(\text{OH})_2\text{D}$  was partially able to suppress hypertrophy [48]. In addition, deletion of VDR stimulated osteoblast-like cell formation of VSMCs and aortic calcification [42,43]. VDR knockout mice also displayed increased thrombogenicity [49]. It has, however, been criticized that the so-called “rescue diet” enriched with calcium, phosphate, and lactose, usually

administered to normalize mineral homeostasis in VDR knockout mice, is not sufficient to prevent secondary hyperparathyroidism. An excessive dietary calcium concentration was required to reduce serum PTH concentrations in the VDR knockout mice to PTH levels measured in wild-type mice. This diet, however, resulted in higher concentrations of circulating FGF23. Considering that PTH and FGF23 exert numerous VDR independent effects, it has been argued that data obtained from VDR knockout mice cannot be attributed solely to vitamin D [50]. The proposed vitamin D effects on the cardiovascular system have also been challenged by findings that despite increased renin concentrations in mice with VDR deletion, the expression of renin and angiotensin II receptors, blood pressure, heart rate, and heart function remained unaltered [51]. Mice with knockout of the gene for VDR (*Vdr*) are discussed in greater detail in Chapter 30.

Vitamin D intoxication, induced by either excess vitamin D doses or administration of (supraphysiologic) doses of  $1,25(\text{OH})_2\text{D}$  to uremic rats, results in hypercalcemia, hyperphosphatemia, massive increase in aortic calcium and phosphate content, and vascular calcification [18]. Moreover, in mice, genetic inactivation of either FGF23 or *klotho* leads to increased serum concentrations of  $1,25(\text{OH})_2\text{D}$ , calcium, and phosphate, and vascular calcifications. Importantly, vascular calcification can be completely eliminated in either FGF23- or *klotho* knockout mice by additional  $1\alpha\text{-OHase}$  (*Cyp27b1*) deletion. This also results in a change from severe hyperphosphatemia to hypophosphatemia [52]. Vascular calcification is also prevented in *klotho*- and sodium/phosphate cotransporters double knockout mice, in which serum levels of phosphate are normalized, but  $1,25(\text{OH})_2\text{D}$  and calcium levels are still elevated [52]. Data support the assumption that the effect of  $1,25(\text{OH})_2\text{D}$  on serum phosphate is crucial for vascular calcification. Results are also in line with the inhibition of atherosclerotic plaque calcification in VDR deficient mice [53], but challenge the effect of experimental vitamin D deficiency on vascular calcification.

Altogether, available data indicate that deficient vitamin D action results in adverse effects on the cardiac system and may result in vascular calcification by stimulation of osteoblast-like cell formation of VSMCs. Excess vitamin D action also results in vascular calcification, a process that is probably mediated by elevated serum phosphate concentration. Nevertheless, some inconsistencies remain, since the effect of VDR deletion on blood pressure and heart function has been questioned [51]. Thus, caution is necessary in extrapolating results from VDR knockout animals to apparently healthy humans with deficient vitamin D status.

## 5. Rickets, osteomalacia, and cardiovascular disease

A number of case reports have associated nutritional rickets with dilated cardiomyopathy, a specific type of heart failure, but not with other forms of CVD, such as hypertension, stroke, or myocardial infarction. Hypocalcemia (plasma calcium  $<2.2$  mol/L) is considered to be an important cause of heart failure in nutritional rickets, and both the cardiac and skeletal effects can effectively be cured by vitamin D and calcium administration [54,55]. In a cohort of 148 neonates with vitamin D deficiency [56], however, echocardiographic assessment was unable to detect signs of heart failure, indicating that heart failure is a rare complication even in vitamin D-deficient infants, or may only be the result of longer lasting vitamin D deficiency. Heart failure, hypertension, or other forms of CVD have also not been described in genetic forms of rickets based on a lack of the  $1\alpha\text{-OHase}$  enzyme or a deletion of the VDR, although these diseases present with hypocalcemia as well [57,58].

Likewise, CVD is not a leading illness in nutritional osteomalacia, although the disease often results in hypocalcemia in the long run [59]. One exception is the case report of nutritional osteomalacia in a middle-aged woman with hypocalcemia and heart failure, and prompt improvement of the cardiac symptoms on correcting the hypocalcemia by vitamin D and calcium [60]. Anyhow, no cases of CVD have been reported in other forms of osteomalacia, such as tumor-related osteomalacia, either. This rare endocrine disorder occurs predominantly in middle-aged adults and is characterized by hypophosphatemia, phosphaturia, and inappropriately low serum levels of  $1,25(\text{OH})_2\text{D}$ . The biochemical changes are related to elevated FGF23 concentrations [61,62].

Collectively, data in children and middle-aged adults indicate that heart failure is a rare illness in severe vitamin D deficiency. Other forms of CVD such as stroke, hypertension, and myocardial infarction are primarily diseases of the aging population, and children and middle-aged adults are probably not a good model for studying the effect of vitamin D deficiency on these diseases.

## 6. Vitamin D status and cardiovascular outcomes in observational studies

Observational studies provide the opportunity to study the association of vitamin D status with CVD risk in large to very large cohorts. Almost all of these studies use the circulating  $25(\text{OH})\text{D}$  concentration as an indicator of vitamin D status. Several metaanalyses (MAs) of prospectively studied cohorts, case-control,

or cross-sectional studies have analyzed the association of circulating 25(OH)D with the risk of hypertension in adults (Table 78.1). Quantitative results show that the risk of incident hypertension decreases by 7%–12% per 25 nmol/L increment in 25(OH)D levels (64,65,67). Results of the most recent MA (67) also indicate an approximate L-shaped correlation between circulating 25(OH)D levels and hypertension risk in the general population. The data are based on prospective cohort studies and include 43,320 participants with 8397 incident cases of hypertension, mostly from Europe and North America. They also show that hypertension risk below 75 nmol/L increases significantly with decreasing 25(OH)D, especially at levels below 50 nmol/L, and also remains significant over the 75–130 nmol/L range [63]. Overall, the risk of hypertension is about 30% higher at circulating 25(OH)D concentration of 25 nmol/L than at 25(OH)D concentration of 75 nmol/L (67).

Various MAs of cohort studies have also analyzed the association of circulating 25(OH)D with other types of CVD, such as stroke, myocardial infarction, ischemic heart disease, heart failure, and CVD mortality (Table 78.2). The MAs are based on up to 850,000 individuals and report nonlinear associations of circulating 25(OH)D with CVD risk. In detail, compared with a circulating 25(OH)D concentration around 75 nmol/L, CVD risk increases at 25(OH)D concentrations below 50 nmol/L and is highest at concentrations below 25 nmol/L. Notably, several of the results presented in Table 78.2 are based on individual participant data [64,65,67,68], and in 1 MA, results are also based on standardized 25(OH)D concentrations [67]. Moreover, results of the aforementioned MAs are adjusted for several other known risk factors of CVD. According to a recent individual participant data MA with a very large number (>400,000) of individuals without a history of CVD [68], the risk of CVD morbidity and CVD mortality are about 16%–36% and 67%, respectively, higher at circulating 25(OH)D concentration <25 nmol/L than at 25(OH)D concentration ≥75 nmol/L. Thus, the data

indicate that circulating 25(OH)D is an independent predictor of CVD risk. Nevertheless, we should keep in mind that cohort studies are prone to unexplained confounding, which prevents the inference of a causal relationship between vitamin D status and CVD based on this type of study.

## 7. Genetic studies on vitamin D and cardiovascular outcomes

Gene polymorphisms can influence vitamin D metabolism and activity at different stages (Fig. 78.1). The presence of these gene variants can be used to study vitamin D effects on clinical outcomes. Genetic studies have the advantage that they are unaffected by lifestyle factors. Therefore, these studies are less susceptible to confounding and reverse causality bias than observational studies. Genetic studies are located at the interface between traditional observational epidemiology and interventional trials.

### 7.1 Mendelian randomization studies

Mendelian randomization (MR) is an analytical method that uses genetic variants as instrumental variables for modifiable risk factors, such as circulating 25(OH)D that potentially affect CVD risk. About seven to eight genes with single-nucleotide polymorphisms (SNPs) have been identified, which affect circulating 25(OH)D and do not have pleiotropic effects [32]. Genetic studies indicate that gene polymorphisms in 7-dehydrocholesterol reductase, vitamin D-binding protein (DBP), hepatic cytochrome P450 family 2 subfamily R member 1 (CYP2R1, also known as vitamin D-25-hydroxylase), and cytochrome P450 family 24 subfamily A member 1 (CYP24A1, also known as 24-OHase) explain up to 8 nmol/L of the variations in serum 25(OH)D [69,181]. Although this effect is lower than the effect achievable by oral vitamin D

Abbreviations: 25(OH)D, 25-hydroxyvitamin D; CI, confidence interval.

supplements or skin synthesis of vitamin D, genetic studies have the important advantage over other study types that they reflect lifelong differences in circulating 25(OH)D.

Some publications using the MR approach have investigated the association of genetically determined 25(OH)D with CVD outcomes [68–76]. They used a focused choice of genetic variants (that is, variants in gene regions related to vitamin D synthesis and metabolism) and used one [74] to four [68,75,76] SNPs to perform the analyses. Another MR [77] used a polygenic choice of genetic variants (that is, all genome-wide significant predictors of 25(OH)D).

An MR analysis showed that 25(OH)D levels were not causally associated with lipid parameters in Chinese or European adults [69]. With respect to blood pressure, neither was strong evidence found for a causal effect of vitamin D status on gestational hypertension or pre-eclampsia [75]. Large MR analyses in male and nonpregnant female adults from cohorts of European ancestry from Europe and North America demonstrated, however, that genetically determined differences in 25(OH)D concentration result in small ( $\leq 0.3$  mmHg), but significant, effects on systolic and/or diastolic blood pressure reduction and an 8% reduction in the risk of hypertension [72,73]. In a large nonlinear MR in individuals of

**FIGURE 78.1** Metabolic pathway of vitamin D with selected enzymes and encoding genes. Several genes encode for enzymes involved in different steps of vitamin D synthesis and metabolism such as 7-dehydrocholesterol synthesis, vitamin D transport in the circulation, 25-hydroxylation, and degradation of 1,25(OH)<sub>2</sub>D. Polymorphisms in these genes may result in reduced or enhanced concentrations of circulating 25(OH)D and 1,25(OH)<sub>2</sub>D, whereas vitamin D receptor polymorphisms potentially influence vitamin D action in target tissues.

European genetic ancestry, curved associations were observed for circulating 25(OH)D with systolic and diastolic blood pressure, with individuals with 25 nmol/L estimated to have 0.70 and 0.25 mmHg higher blood pressure compared with 50 nmol/L [77]. Thus, data indicate small, but significantly beneficial, effects on blood pressure in adults in the long run.

Several MR analyses did not demonstrate causal associations of genetically determined 25(OH)D levels with vascular diseases such as myocardial infarction, stroke, ischemic heart disease, ischemic stroke, subarachnoid hemorrhage, intracerebral hemorrhage, or cardiovascular mortality in Chinese, North American, and European people [69–71,74,76]. However, because the participants of these investigations were adults of different ages, results of many individuals might reflect the association between 25(OH)D and disease progression, rather than disease occurrence. Moreover, the aforementioned MR analyses did not account for baseline vitamin D status. Therefore, data of a very large MR analysis by Sofianopoulou et al. [68] in individuals of European ancestries (from the UK Biobank dataset as well as three smaller datasets) with no known history of coronary heart disease or stroke at baseline are of utmost importance. This investigation reported no associations of genetically predicted 25(OH)D with coronary heart disease, stroke, or cardiovascular mortality in population-wide genetic analyses. Most importantly, however, among

the strata of vitamin D–deficient participants (25(OH)D concentration below 25 nmol/L), genetic analyses provided strong evidence for an inverse association with cardiovascular mortality, and suggestive evidence of inverse associations for stroke and coronary heart disease. In detail, per 10 nmol/L higher genetically predicted 25(OH)D concentration, the chance of CVD mortality, stroke, and CHD was in the vitamin D deficiency strata on average reduced by 31%, 15%, and 11%, respectively. In another nonlinear MR by Zhou et al. [77] that used broadly the same data as the nonlinear MR by Sofianopoulou et al. [68], individuals with circulating 25(OH)D at 25 nmol/L had significantly (11%) higher odds of CVD (composite of coronary artery disease, stroke, and peripheral vascular disease) compared with those with 50 nmol/L. There appeared to be a very slight further lowering in the odds of CVD with higher concentrations, and for example, participants with 75 nmol/L had 2% lower odds compared with 50 nmol/L, indicating beneficial vitamin D effects up to circulating 25(OH)D of 75 nmol/L. Correction of circulating 25(OH)D level below 50 nmol/L was predicted to result in a 4.4% reduction in CVD incidence and further increased to 5.7% at 75 nmol/L [77]. However, there are concerns that the effects on CVD risk may be overestimated [78], since Zhou et al. [77] used a polygenic choice of genetic variants (35 genome-wide significant predictors of 25(OH)D), whereas Sofianopoulou

et al. [68] used a focused choice of genetic variants (four gene regions related to vitamin D synthesis and metabolism). Therefore, it has been argued that results in the study by Zhou et al. may be partly attributable to pleiotropic associations of the genetic variants in the analysis, especially in the strata of circulating 25(OH)D above 25 nmol/L [78]. The use of MR in analyzing the potential impact of vitamin D status on human health is discussed in greater detail in [Chapter 61](#).

## 7.2 Polymorphisms in the VDR gene and cardiovascular outcomes

Another group of genetic studies have analyzed the association of variants in genes encoding proteins, which may influence vitamin D metabolism or vitamin D signaling pathways, with CVD risk ([Fig. 78.1](#)). The gene encoding the VDR protein is located on chromosome 12. Several functional VDR SNPs are known: BsmI and ApaI in intron 8, TaqI in exon 9, and FokI in exon 2. In these mutations, the base cytosine is replaced by thymine (FokI), guanine by adenine (BsmI), thymine by guanine (ApaI), and thymine by cytosine (TaqI). A number of metaanalyses reported significant associations of Apa 1, Fok 1, Taq 1, and Bsm 1 polymorphisms of the VDR gene with parameters of CVD risk, such as hypertension, vascular and microvascular complications, or coronary artery disease [79–83]. One MA reported no associations of these gene variants with coronary artery disease [84]. However, none of the aforementioned MAs reported *P*-values for the described associations of  $<10^{-7}$ , which is considered to be the threshold for reliable causal associations of a gene polymorphism with a disease outcome. The numbers of included cases and controls ranged from 2306 to 8011, and from 1635 to 4860, respectively. For genetic studies, these numbers were relatively small. Therefore, it cannot be ruled out that the MAs were statistically underpowered to demonstrate strong associations between VDR polymorphisms and CVD risk.

## 7.3 Polymorphisms in the CYP24A1 gene and cardiovascular outcomes

The CYP24A1 gene is located on chromosome 20. This gene, encoding for the 24-OHase, is responsible for the catabolism of 25(OH)D and 1,25(OH)2D and thus for the regulation of the concentration of these two vitamin D metabolites in the circulation. CYP24A1 is induced by 25(OH)D, 1,25(OH)2D, and FGF23 and is one of the most highly inducible genes in humans, capable of increasing its transcription 20,000-fold [85]. Several genetic variations of the

CYP24A1 gene are known. The association of polymorphisms in the CYP24A1 gene was analyzed in a metaanalysis in three independent populations, including 3657 individuals [86]. In the MA, the C allele (minor allele frequency ranging from 0.25 to 0.31 across the three populations) was associated with lower coronary artery calcification, yielding a *P*-value close to the aforementioned threshold of  $10^{-7}$  ( $2.9 \times 10^{-6}$ ). Moreover, in Chinese people, genetic variations of the CYP24A1 gene were significantly associated with susceptibility to hypertension [87]. However, further functional studies are needed to provide more evidence on how genetic variants of the CYP24A1 gene affect hypertension susceptibility.

## 8. Vitamin D supplementation studies

### 8.1 Vitamin D effects on biochemical risk markers

RCTs provide the highest level of scientific evidence. Studies on biochemical markers can provide insights into short-term and mid-term vitamin D effects regarding CVD risk. These markers include traditional risk markers such as lipid parameters and nontraditional risk markers such as PTH and FGF23 (see earlier sections), inflammation markers, and parameters of the RAAS.

#### 8.1.1 Lipid parameters

Dyslipoproteinemia is a well-known risk factor for CVD. There is a link between cholesterol and vitamin D since the precursor of vitamin D, 7-dehydrocholesterol, can not only be converted by solar UVB radiation to previtamin D<sub>3</sub>, but alternatively also by an enzymatic reaction, mediated by the enzyme 7-dehydrocholesterol-reductase, to cholesterol. A large MA has summarized data from RCTs regarding the effect of vitamin D supplementation on lipid parameters in adults [88]. The average vitamin D dose was 3000 IU/day; two-thirds of the studies had mean baseline 25(OH)D levels  $<50$  nmol/L, and the increase in circulating 25(OH)D was  $48 \pm 23$  nmol/L. Data indicate small, but significant, reductions in total cholesterol, LDL cholesterol, and triglycerides of  $-0.15$  mmol/L,  $-0.10$  mmol/L, and  $-0.12$  mmol/L, respectively, and an increase in HDL cholesterol of  $0.09$  mmol/L by vitamin D supplementation. However, there was no significant vitamin D effect according to baseline 25(OH)D concentration or daily vitamin D dose on lipid parameters. Similar effects of vitamin D supplementation were reported in another MA [89] for total cholesterol, LDL cholesterol, and triglycerides. In contrast to the

aforementioned metaanalysis, a nonsignificant decrease of  $-0.10$  mmol/L was reported for HDL cholesterol. In that MA, the improvements in total cholesterol and triglycerides were more pronounced in participants with baseline 25(OH)D below 50 nmol/L than in individuals above this level [89]. In children and adolescents, vitamin D supplementation did not affect lipid parameters, with the exception of a reduction in triglycerides by 25 mg/dL in the subgroup of individuals with a total vitamin D supplementation  $\geq 200,000$  IU [90]. However, all included four RCTs were very small trials, so the results need to be confirmed by larger studies.

### 8.1.2 PTH and FGF23

With respect to PTH, it is well known that the effect of vitamin D on this hormone is influenced by various factors such as initial 25(OH)D and initial PTH concentrations, vitamin D dose, frequency of vitamin D administration, concomitant calcium intake, and body weight and composition [91]. An MA of RCTs has demonstrated that in apparently healthy individuals with initial 25(OH)D  $< 50$  nmol/L and  $\geq 50$  nmol/L, vitamin D supplementation suppresses serum PTH on average by 17 pg/mL and 2 pg/mL, respectively, indicating a threshold of PTH concentrations around 50 nmol/L [92]. In patients with heart failure and CKD, the suppression of serum PTH by vitamin D supplementation was on average 13 pg/mL and 32 pg/mL, respectively [93,94], whereas vitamin D supplementation did not significantly influence serum PTH, but resulted in a significant increase in phosphorus levels in patients on dialysis [95]. In another MA in patients with CKD, the effect on the suppression of serum PTH was more pronounced by administration of active vitamin D metabolites or analogs than by native vitamin D supplementation [91]. FGF23 remains unaffected by vitamin D supplementation up to doses of 3000 IU daily, whereas higher daily dose equivalents or activated vitamin D significantly increase FGF23 concentrations [96,97]. The effect of vitamin D administration on FGF23 increment is higher in patients with end-stage kidney/heart failure than in other individuals [96]. Altogether, vitamin D supplementation suppresses PTH levels, but dose-dependently also increases FGF23 concentrations.

### 8.1.3 Renin–angiotensin–aldosterone system

Activation of the RAAS plays a pivotal role in the etiology of hypertension and other CVDs such as heart failure. Due to the high prevalence of these diseases, various drugs targeting the RAAS have been developed, such as renin inhibitors, angiotensin-converting enzyme inhibitors, angiotensin 1-receptor antagonists, diuretics, and mineralocorticoid receptor antagonists (Fig. 78.2). The frequent use of these drugs in the adult population

complicates isolated investigations on the effect of vitamin D on the human RAAS system. Nevertheless, the effect of vitamin D supplementation on parameters of the RAAS (renin, angiotensin II, aldosterone) has been investigated in different patient groups, including patients with insufficient vitamin D status [98–100], non-insulin-dependent diabetes mellitus [101–103], heart failure [104–107], and CKD [108,109]. The vast majority of studies reported no significant effect on parameters of the RAAS. In detail, vitamin D was ineffective in studies investigating patients with insufficient/deficient vitamin D status [98–100] or CKD [108,109]. With respect to heart failure, two studies reported no significant effects [104,105], and one study each reported a significant decrease in plasma renin [106] or aldosterone [107]. In diabetic patients, no effect of vitamin D on RAAS parameters was reported in two studies [101,103] and a decrease in plasma renin in one study [102].

### 8.1.4 Inflammation parameters

With respect to C-reactive protein (CRP), an MA reported a small suppression of  $-0.20$  mg/L by vitamin D supplementation [88]. This effect on CRP seems to be dose-dependent since daily vitamin D doses  $< 1000$  IU had no beneficial effect, whereas doses  $\geq 1000$  IU/d had a favorable effect. Moreover, metaregression indicated that older age predicted a significant decrease in CRP and IL-6 [110]. In patients with HF, a disease resulting in high concentrations of inflammation markers, the effect of vitamin D on inflammation is inconsistent since no significant effect has been reported [111], as well as a suppression in CRP [112]. Moreover, a significant suppression of the proinflammatory cytokine tumor necrosis factor- $\alpha$  was reported, whereas concentrations of interleukin-6 remained unaffected. It was concluded that vitamin D supplementation may have specific, but modest effects on inflammatory markers in this group of patients [111]. Irrespective of some inconsistencies and open uncertainties such as the effect of baseline and achieved circulating 25(OH)D, vitamin D dose, age effects, and disease-specific effects, it is noteworthy that accumulating evidence does not support a causal effect of inflammation on CVD risk [113,114], thereby questioning the use of inflammatory parameters as CVD risk markers.

## 8.2 Vitamin D effects on parameters of cardiovascular function

### 8.2.1 Vascular and cardiac function

Functional parameters represent the interface between biochemical risk markers and clinical events. Vascular function is influenced by the interactions

**FIGURE 78.2** Interrelationships between the renin–angiotensin–aldosterone system (RAAS), parathyroid hormone, and the cardiovascular system. Renin synthesizes angiotensin I (ang I) from angiotensinogen. Ang I is further cleaved to angiotensin II (ang II) by angiotensin-converting enzyme (ACE). Ang II acts on angiotensin 1 and 2 receptors (AT1R, AT2R), resulting in vasoconstriction and renal tubular reabsorption of sodium. Ang II also activates aldosterone secretion. Aldosterone acts on mineralocorticoid receptor (MCR) by retaining water and promoting sodium retention. The RAAS can be blocked at different stages by renin inhibitors, ACE inhibitors, angiotensin receptor blockers (ARBs), and mineralocorticoid antagonists (MCRAs). Primary aldosteronism (PA) results in hyperparathyroidism (HPT). Vitamin D deficiency also results in HPT. HPT promotes vasoconstriction and probably also activates the RAAS by stimulation of renin, ang II, and aldosterone activity. Vascular function can be assessed by the measurement of blood pressure (BP), pulse wave velocity (PWV), augmentation index (AIx), and dilation flow-mediated dilation (FMD). Cardiac function can be assessed by measurement of left ventricular ejection fraction (LVEF) and left ventricular end-diastolic diameter (LVEDD).

among endothelial cells, VSMCs, adventitial tissues, and inflammatory cells. Vascular function can be assessed by measuring aortic pulse wave velocity (PWV, the velocity at which the blood pressure pulse propagates through the circulatory system) and augmentation index (AIx, the ratio of late systolic pressure to early systolic pressure). Both parameters are accepted measures of arterial stiffness. High PWV and AI values are considered unfavorable. Ultrasonographic measurement of flow-mediated dilation (FMD, dilation of an artery when blood flow increases in that artery following a transient period of forearm ischemia) can be used to assess endothelial function. Low values are considered unfavorable.

Echocardiographic measurements of left ventricular ejection fraction (LVEF) and left ventricular end-diastolic diameter (LVEDD) are frequently used tools to assess cardiac function and the risk of heart failure. LVEF values below 50% indicate a reduced stroke volume of the heart. The reference range for LVEDD is 33–56 mm, whereas CVDs, such as heart failure, are associated with elevated values.

The effect of vitamin D supplementation on vascular and cardiac function has recently been summarized [28]. Trial-level as well as individual-patient-level data showed no consistent effect of vitamin D supplementation on PWV, AI, or FMD, but a beneficial effect of a daily

vitamin D dose  $\geq 2000$  IU on PWV cannot be excluded. Results are based on trials with a duration of 4–57 weeks and daily doses of 600–7100 IU. With respect to cardiac function in patients with heart failure, a dose-dependent beneficial effect was considered on LVEF (+4.2%) and LVEDD (–2.3 mm) in trials with doses of 1000–7100 IU vitamin D daily [28]. A more recent MA supported the beneficial effect of vitamin D supplementation on LVEF in patients with heart failure (+3.3%). Although substantial heterogeneity among trials was reported in that MA, which so far included the largest number of trials and study participants, a dose-dependent effect could not be confirmed in this analysis [115]. It is also noteworthy that heart failure with preserved LVEF accounts for about 40%–50% of incident heart failure cases overall [116]. In this group of patients, the effect of vitamin D on LVEF may be absent or of limited clinical relevance, as well as in individuals without heart failure.

### 8.2.2 Hypertension

Besides the aforementioned vascular and cardiac parameters, blood pressure is another major parameter influencing clinical CVD events [117]. Hypertension (systolic blood pressure  $\geq 140$  mmHg; diastolic blood pressure  $\geq 90$  mmHg) is a risk factor for coronary artery disease, myocardial infarction, heart failure, and cerebrovascular stroke. The aforementioned MA by Mirhosseini et al. [88] included 39 RCTs in their analysis on blood pressure and reported a small, but significant reduction in systolic blood pressure of –0.10 mmHg and of –0.07 mmHg in diastolic blood pressure by vitamin D supplementation. The effects were more pronounced if in-study 25(OH)D  $\geq 86$  nmol/L were achieved, the daily vitamin D dose was  $\geq 4000$  IU, and the duration of intervention was  $\geq 6$  months. Results cover the 95% CI of an MA incorporating individual patient data from 27 RCTs, concluding that vitamin D supplementation is ineffective as an agent for lowering blood pressure [118]. In the latter analysis, trial-level metaregression found no significant relationship between systolic or diastolic blood pressure and daily vitamin D<sub>3</sub> dose equivalent, study duration, baseline PTH concentration, and baseline 25(OH)D. In line with these data, two more recent MAs reported that vitamin D does not influence blood pressure in children and adolescents [90] or the general adult population [63]. However, there is some evidence that in elderly hypertensive patients, vitamin D supplementation reduces systolic and diastolic blood pressure on average by –4.0 mmHg and –2.2 mmHg, respectively [119]. Likewise, there is evidence that vitamin D supplementation may reduce the risk of incident preeclampsia in pregnant women [120], a disease that manifests as hypertension, edema, and proteinuria.

## 9. Cardiovascular events in large vitamin D supplementation trials in general populations

The Holy Grail of evidence-based medicine is an adequately powered RCT with a treatment that can impact a clinically relevant primary endpoint. Four large randomized controlled vitamin D supplementation trials [121–124], focusing on CVD outcomes, such as hypertension or CVD events, have been performed in the general elderly (>50 years, >55 years, >60 or 65 years, and >70 years, respectively) population during recent years. These trials were performed in New Zealand (Vitamin D Assessment trial, ViDA), the United States (Vitamin D And Omega-3 Trial, VITAL), and Europe (Vitamin D3–Omega-3–Home Exercise–HeALTHy Ageing and Longevity Trial, DO-Health; Finnish vitamin D trial, FIND). ViDA, VITAL, DO-Health, and FIND included 5110, 25,871, 2157, and 2495 males and females, respectively, with a median study duration of 3.3 years in ViDA, 5.3 years in VITAL, 5.0 years in FIND, and a treatment duration of 3 years in Do-Health. In the treatment arms, study participants received a monthly bolus dose of 100,000 IU vitamin D<sub>3</sub> (ViDA), 2000 IU vitamin D<sub>3</sub> daily (VITAL, DO-Health), and 1600 or 3200 IU daily (FIND). In all four trials, the control group received a placebo. In the four trials, mean baseline circulating 25(OH)D concentrations were above 50 nmol/L, and mean in-study 25(OH)D concentrations increased to at least 94 nmol/L. Primary endpoints were blood pressure (DO-Health) or a composite of fatal and nonfatal CVD events (ViDA, VITAL, and FIND).

In DO-Health [123], vitamin D supplementation did not significantly influence systolic or diastolic blood pressure values. In ViDA [121], vitamin D supplementation neither significantly influenced the primary endpoint nor secondary endpoints, such as myocardial infarction, angina pectoris, heart failure, hypertension, arrhythmias, arterio sclerosis, stroke, and venous thrombosis. Similarly, in VITAL [122] and FIND [124], vitamin D supplementation neither significantly affected a composite of nonfatal and fatal CVD events nor an expanded composite of major cardiovascular events plus coronary revascularization. In none of the RCTs did results change substantially when analyses were restricted to study participants with baseline 25(OH)D concentrations <50 nmol/L. Unfortunately, however, none of the trials reported outcome data in the subgroup of study participants with baseline 25(OH)D concentrations <25–30 nmol/L, although it is also noteworthy that the prevalence of individuals with such low concentrations was apparently very low in all four trials. The D-Health trial is an ongoing Australian study with 21,315 recruited elderly participants receiving a monthly bolus dose of 60,000 IU vitamin D or placebo over 5 years

for prevention of mortality. Neither all-cause mortality nor CVD mortality was significantly influenced by vitamin D supplementation [125]. This study will also capture nonfatal cardiovascular events through self-reports in annual surveys [126]. However, since baseline 25(OH)D concentrations were on average 77 nmol/L [125], a beneficial vitamin D effect on nonfatal CVD events seems to be unlikely as well.

Independent of frequency and dosing of vitamin D, all aforementioned large trials documented null effects with respect to CVD-related outcome parameters. Results are in general agreement with metaanalyses of RCTs [118,127–130] and an umbrella review of RCTs [131], which included trials where CVD outcomes were only secondary endpoints. However, none of these studies focused on individuals with vitamin D deficiency, i.e., circulating 25(OH)D < 25–30 nmol/L.

## 10. Vitamin D in end-stage organ failure

In CKD and end-stage heart failure, secondary hyperparathyroidism, low 25(OH)D and 1,25(OH)<sub>2</sub>D concentrations, and elevated phosphate concentrations are prevalent [132–135] (see [Chapter 79](#)). In CKD, CVD is a leading cause of overall mortality and a predictor of CVD mortality [135]. Patients with CKD or chronic heart failure enter a vicious circle, named cardiorenal or renocardial syndrome, where functional impairment of one organ affects the function of the other. At present, it remains unclear whether in these diseases the aforementioned changes in the PTH–vitamin D axis are causally related to CVD events.

An MR analysis suggested even harmful actions of vitamin D on kidney function, since it indicated a negative causal effect of log transformed 25(OH)D on log-transformed eGFR. Results showed that a 10% increase in serum 25(OH)D levels causes a 0.3% decrease in eGFR. A significant harmful association was also reported for 1,25(OH)<sub>2</sub>D on eGFR [136]. Although significant, the effect of vitamin D on eGFR was, however, small, and an ancillary study to the VITAL trial in 1312 participants with diabetes mellitus at baseline showed no difference in eGFR changes or albuminuria over 5 years of treatment with vitamin D compared with placebo [137]. These data support the assumption that long-term supplementation of 2000 IU is safe with respect to kidney function. A reanalysis of the extended-release calcifediol trials in CKD patients that used doses of 25(OH)D resulting in very high circulating 25(OH)D concentrations (study duration 26 weeks) found no significant differences in biochemical safety parameters, such as plasma calcium, phosphate, FGF-23, and eGFR, even up to mean circulating

25(OH)D concentrations of 235 nmol/L [138]. With respect to clinical endpoints, observational studies (21 studies, 221,610 patients) actually indicate a risk reduction in CVD mortality of 45% by bolus administration of high vitamin D doses or the administration of activated vitamin D [139]. However, an MA of RCTs (17 studies, 1819 patients) reported only a nonsignificant reduction in CVD mortality of 7% by administration of vitamin D or activated vitamin D [139]. Again, results indicate caution regarding overinterpretation of observational data. In line with this assumption, a relatively large trial [140] in patients with secondary hyperparathyroidism undergoing maintenance hemodialysis (976 patients) reported that the risk of a composite measure of fatal and nonfatal cardiovascular events even tended to be 36% higher in patients receiving activated vitamin D versus usual care, when the per protocol set was analyzed.

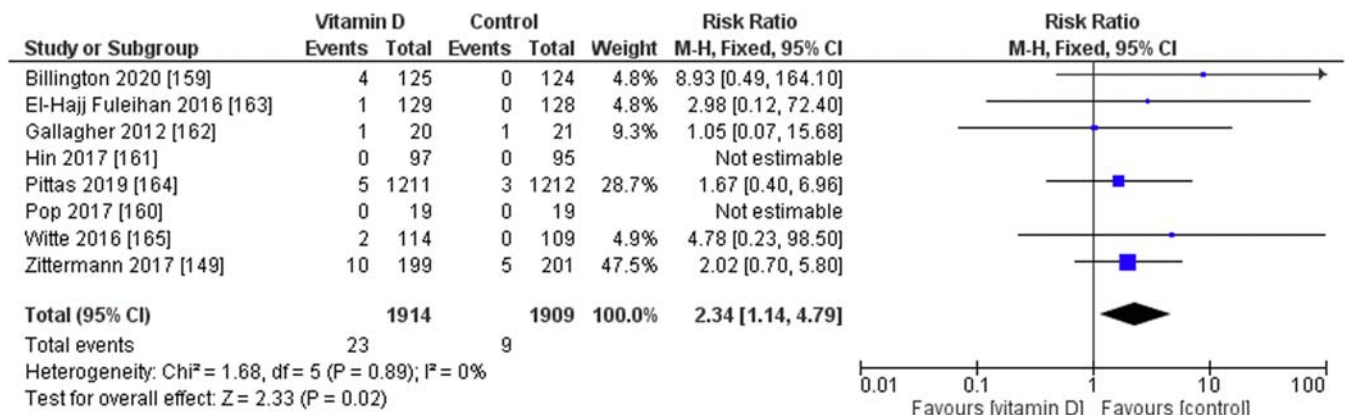

In end-stage heart failure, data regarding the effect of vitamin D supplementation on clinical events are scarce. In patients awaiting heart transplantation, 3 years of daily vitamin D supplementation with 4000 IU did not significantly influence the primary endpoint (overall mortality), but increased the need for mechanical circulatory support implantation [141]. Since the higher risk of mechanical circulatory support implant disappeared in the vitamin D group during a 3-year postintervention follow-up, data support the assumption of adverse vitamin D effects on the cardiovascular system at doses of 4000 IU daily in patients with advanced heart failure [142]. Moreover, vitamin D supplementation of 4000 IU daily did not significantly influence the prevalence of secondary hyperparathyroidism and the concentration of FGF23 [104,143]. Thus, a suggested beneficial effect of vitamin D in advanced heart failure is challenged by these data. Since PTH not only has harmful effects on the cardiovascular system but is also considered to increase myocardial blood flow and cardiac output, it has been suggested that in some patients, high PTH concentrations may, at least in part, be the result of an adaptation process to the severity of the disease, rather than the result of low vitamin D metabolite concentrations [134]. Surprisingly, in end-stage heart failure, low and not high PTH concentrations were predictive of poor clinical outcome [144]. Probably, low PTH concentrations together with low 1,25(OH)<sub>2</sub>D and high FGF23 concentrations prevent patients with failing hearts from more severe derangements in mineral metabolism, such as acute calcium and phosphate intoxication [14]. In addition, immobilization may result in calcium release from bone, leading to a suppression in circulating 1,25(OH)<sub>2</sub>D and PTH concentrations. Overall, it seems that in patients with kidney or heart failure, no simple association exists between vitamin D status, PTH, FGF23, and CVD risk.

## 11. Adverse vitamin D effects on the cardiovascular system

For the general population, the Institute of Medicine has set the upper threshold of adequate circulating 25(OH)D concentrations at 125 nmol/L and the upper tolerable intake level for vitamin D at 4000 IU [11]. In line with the circulating 25(OH)D threshold, individual participant data MA in European individuals, mostly from the general population, reported no significantly increased CVD morbidity or mortality at 25(OH)D concentrations between 100 and 140 nmol/L [67,68]. Likewise, another MA did not provide evidence for an increased risk of CVD events at 25(OH)D levels between 100 and 137 nmol/L in the general population [66]. Similar results were also reported in a rural Chinese population [145]. In contrast, several observational studies in the clinical setting reported a U-shaped or inverse J-shaped association of circulating 25(OH)D with CVD risk [146–149]. Data indicate that the risk of CVD events may already be increased at 25(OH)D levels above 100 nmol/L. The cause of this association remains largely unknown. Potential explanations include the possibility that high 25(OH)D levels (1) reflect low availability of the active vitamin D hormone 1,25(OH)<sub>2</sub>D and may thus be indicative of deficient rather than excess vitamin D action, (2) are related to individuals with the *APOE ε 4* gene, which is associated with an increased CVD risk, and (3) are associated with excess intestinal calcium absorption resulting in hypercalcemia [147].

With regard to the risk of hypercalcemia, a generally accepted indicator of vitamin D intoxication, data are available from some long-term (>1 year) randomized controlled trials on supplementation with 4000 IU of vitamin D daily [141,150–156], a dose considered to be the upper tolerable intake level [11,157]. In these studies,

the weighted mean baseline 25OHD concentration was 62 nmol/L, and the weighted mean increase in the vitamin D versus control group was 61 nmol/L, resulting in mean circulating 25(OH)D concentrations of about 123 nmol/L. The absolute incidence of hypercalcemia (>2.6 mmol/L up to > 2.75 mmol/L, depending on definition) in the vitamin D supplemented and control groups was 1.20% and 0.52%, respectively (Fig. 78.3). Likewise, in another MA of long-term (≥24 weeks) vitamin D supplementation, which included all eligible RCTs, irrespective of the vitamin D dose administered, the absolute incidence of hypercalcemia was in the vitamin D-supplemented groups significantly higher than in the control groups (1.03% vs. 0.54%) [158]. A vitamin D-mediated cause of hypercalcemia are biallelic and, in some instances, monoallelic loss-of-function mutations in the *CYP24A1* gene. The diseases are associated with elevated serum 1,25(OH)<sub>2</sub>D concentrations, suppressed PTH concentrations, hypercalciuria, nephrocalcinosis, and hypertension [159,160]. The prevalence of hypercalcemia-related *CYP24A1* mutations in the general population is unknown [161], but may be about 1:33,000 births in Europe [159]. Overall, even when the upper tolerable intake is not exceeded, vitamin D supplementation appears to increase the risk of hypercalcemia in a small proportion of individuals. The clinical importance of small elevations in serum calcium is highlighted by findings that (1) heart failure incidence increases progressively from serum calcium of 2.25 mmol/L up to 2.75 mmol/L [162] and (2) genetically predicted lifelong higher concentrations of serum calcium may shorten life expectancy and increase CVD risk [163]. Even a low incidence of adverse vitamin D effects may have substantial consequences at a population level. It cannot be ruled out that the effect on prandial or postprandial serum calcium is even more pronounced than on the frequently collected

**FIGURE 78.3** Effect of vitamin D supplementation of 4000 IU daily on the risk of hypercalcemia. Vertical marks represent hypercalcemia risk, and horizontal bars represent 95% CIs; a statistically significant result was assumed when the 95% CI did not include 1 (vertical line). Note that two studies reported no case of hypercalcemia.

fasting blood samples, since a daily vitamin D dose of 4000 IU increases intestinal calcium absorption rate significantly (by about 6%–7%) [164].

Whereas large vitamin D supplementation trials in the general older population with average in-study circulating 25(OH)D concentrations of 104 and 132 nmol/L did not provide evidence for adverse vitamin D effects on the cardiovascular system [120,121], in critically ill heart failure patients, 3-year vitamin D supplementation increased in-study 25(OH)D concentrations to 100–110 nmol/L on average, and also increased the risk of poor clinical outcome significantly [140,165]. Moreover, impaired kidney function is considered to contribute to the loss of homeostatic control of serum calcium concentration and may thus influence the cutoff point defining vitamin D toxicity [11]. Therefore, there continues to be large uncertainty about the progressive health effects of regular ingestion of moderately high amounts of vitamin D in the long term. Altogether, especially in the clinical setting, long-term vitamin D supplementation with moderately high doses should be performed with caution and only based on clear medical indications. Upper tolerable intake levels of vitamin D and adequate circulating 25(OH)D concentrations generated for the apparently healthy general population should not a priori be adopted in the clinical setting.

## 12. Conclusion

Data regarding vitamin D and CVD are puzzling: experimental data demonstrate various beneficial, but also harmful vitamin D effects on the cardiovascular system. Some of these effects may be mediated not only by vitamin D itself, but also by hormones regulating vitamin D metabolism such as PTH and FG23. Large observational studies support an inverse association of vitamin D deficiency with CVD risk. Despite this accumulating evidence regarding detrimental effects of vitamin D deficiency on the cardiovascular system, CVD is, however, rarely seen in patients with nutritional rickets or genetic causes of rickets and osteomalacia, probably because CVD is primarily a disease of the aging population. In addition, the available studies may have been too small to capture the potentially small vitamin D effects on CVD risk. Moreover, there is no strong evidence for beneficial effects of vitamin D supplementation on biochemical risk markers, functional parameters of the cardiovascular system, or CVD events. Nevertheless, in the vast majority of trials, study participation was not restricted to vitamin D deficient adult individuals, i.e., people with baseline initial 25(OH)D concentrations <25–30 nmol/L. Therefore, two large MR investigations [68,77], a study type that

is able to assess lifelong differences in vitamin D status, are of utmost importance, because they indicate that deficient 25(OH)D concentrations increase the risk of CVD morbidity and mortality. Moreover, there is some evidence that gene variants influencing cellular vitamin D action or vitamin D catabolism may influence CVD risk [77–81,83]. However, further studies have to show whether enhanced and/or prolonged cellular vitamin D actions reduce or increase CVD risk. Nevertheless, some data indicate that in future a more personalized vitamin D supplementation advice may become possible [166]. Meanwhile, the entire group of individuals with circulating 25(OH)D concentrations <25–30 nmol/L should be the target population with respect to the prevention of any vitamin D deficiency–related CVD risk. In addition, circulating 25(OH)D concentration above 100–125 nmol/L should be avoided, especially in the clinical setting, to prevent harmful vitamin D effects on the cardiovascular system.

Inadequate vitamin D status is a worldwide issue. The prevalence of vitamin D deficiency (<25–30 nmol/L) in the entire adult population in the United States and Europe is 8% and 13%, respectively, but is considerably higher in Afro-Americans (32%) and non-European immigrants (up to 50% and more) [167,168]. In several low- to middle-income countries, the prevalence of deficient circulating 25(OH)D concentrations is between 40% and 90% in some groups of the general population, such as children, women, and older adults [169]. Even if sun exposure and thus skin synthesis of vitamin D are limited or absent, the officially recommended daily vitamin D doses for adults of 600–800 IU daily should be effective in preventing circulating 25(OH)D concentrations <25–30 nmol/L in the vast majority of individuals [170]. This dose would also be far removed from harmful effects of vitamin D excess on the cardiovascular system. Since results of the aforementioned large MRs [68,77] are based on individuals with no known history of coronary heart disease or stroke at baseline, prevention of vitamin D deficiency should start as early as possible. To erase vitamin D deficiency globally, (mandatory) vitamin D food fortification rather than the (individual) use of vitamin D supplements would be most promising [171].

## 13. Summary points

- Several lines of evidence such as ecological data, experimental animal studies, observational studies, and Mendelian randomization studies indicate a detrimental effect of vitamin D deficiency on the cardiovascular system and CVD outcomes.

- Although studies in patients with rickets or osteomalacia as well as vitamin D supplementation trials were largely unable to support beneficial vitamin D effects on CVD risk, several study limitations may have been responsible for these null effects.
- Individuals with circulating 25(OH)D concentrations <25–30 nmol/L should be the target population for the prevention of any adverse effect of vitamin D deficiency on the cardiovascular system.
- The officially recommended oral vitamin D doses of 600–800 IU should be able to prevent deficient circulating 25(OH)D concentrations in the vast majority of adult individuals.
- Since there is evidence for a U-shaped or inverse J-shaped association of circulating 25(OH)D with CVD risk, especially in the clinical setting, long-term vitamin D supplementation with moderately high doses should be performed with caution and only based on clear medical indications.

# Vitamin D and renal disease

Adriana Dusso<sup>1</sup>, Kevin T. Bauerle<sup>2</sup>,  
Rong Mei Zhang<sup>1</sup> and Carlos Bernal-Mizrahi<sup>3</sup>

<sup>1</sup>Division of Endocrinology, Metabolism and Lipid Research, Washington University, St Louis, MO, United States <sup>2</sup>Saint Louis VA Medical Center, Division of Endocrinology, Metabolism and Lipid Research, Washington University, St Louis, MO, United States <sup>3</sup>Saint Louis VA Medical Center, Biology and Cell Physiology, Division of Endocrinology, Metabolism and Lipid Research, Washington University, St Louis, MO, United States

## OBJECTIVES

- Present the basic pathophysiological mechanisms underlying CKD-induced vitamin D deficiency and disruption of renal and extra-renal vitamin D bio-activation and catabolism.
- Detail the pro-survival actions of the 1,25(OH)<sub>2</sub>D–VDR complex, which oppose the accelerated aging of the skeletal, immune, renal, and cardiovascular systems in CKD.
- Highlight the role of vitamin D maintenance of the FGF23/klotho axis in avoiding the renal and cardiovascular damage associated with hyperphosphatemia, low serum klotho, high FGF23, and excess active vitamin D in CKD.
- Emphasize the importance of correcting vitamin D deficiency prior to initiation of 1,25(OH)<sub>2</sub>D (or analog) in the clinical setting.
- Discuss current recommendations regarding supplementation strategies to correct vitamin D deficiency with CKD progression.

## 1. Introduction

The vitamin D endocrine system is essential for human health, and a normal kidney is critical to maintain the functional integrity of the vitamin D endocrine system. Large epidemiological studies in normal individuals have demonstrated that vitamin D deficiency is

associated with an increased relative risk for cardiovascular and all-cause mortality [1,2]. In chronic kidney disease (CKD), a disorder affecting more than 10%–12% of the world population, the progressive loss of the capacity of the injured kidney to maintain the functional integrity of the vitamin D endocrine system contributes to accelerated skeletal, immune, renal, and cardiovascular aging, resulting in a 10–20-fold increase in morbidity and mortality compared with gender and age-matched individuals with normal renal function [3,4].

Strong molecular basis for the adverse impact of abnormal kidney function on the vitamin D endocrine system emerged in 1971 with the discovery that the kidney is the main site for the synthesis of 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D or 1,25(OH)<sub>2</sub>D), the hormonal form of vitamin D [5] and the most potent endogenous metabolite to activate the vitamin D receptor (VDR) [6]. In 1984, 1,25(OH)<sub>2</sub>D replacement therapy in advanced CKD patients was utilized to counteract the impaired intestinal calcium absorption and increased synthesis and secretion of parathyroid hormone (PTH). The latter resulted in defective bone mineralization, increased fracture risk, and soft tissue and vascular calcification [7] (see the interactions of the calcium/1,25(OH)<sub>2</sub>D/PTH axis summarized in Fig. 79.1). Over the past 4 decades, studies aimed at overcoming the challenges of effectively controlling secondary hyperparathyroidism (SHPT) with 1,25(OH)<sub>2</sub>D replacement therapy, while avoiding skeletal and cardiovascular risks, have greatly expanded our understanding of the pathogenesis of disrupted vitamin D metabolism and its protective actions in the course of CKD progression. These studies have led to three critical paradigm shifts in our understanding of vitamin D metabolism and

**FIGURE 79.1** Central role of renal calcitriol production in mineral and skeletal homeostasis. Renal 1,25(OH)<sub>2</sub>D (1,25D) production tightly controls the complex hormonal feedback loops between PTH and FGF23/klotho, as well as Ca (black arrows) and P (gray arrows) fluxes between the intestine, bone, and the kidney that ensure normal mineral homeostasis and skeletal integrity, while preventing the excess of both ions predisposing to ectopic calcifications and the proinflammatory, proaging actions of hyperphosphatemia. Kidney disease impairs the renal uptake of 25(OH)D, calcitriol synthesis, and the maintenance of renal klotho causing severe abnormalities in the calcitriol/FGF23-klotho/PTH loops (see text for details) accelerating the development of hyperphosphatemia, bone loss, propensity to fractures, soft-tissue calcifications, renal and cardiovascular damage, and high mortality rates. PTH, parathyroid hormone; FGF23, fibroblast growth factor-23.

actions that continue to shape the clinical application of vitamin D interventions in CKD: (1) The development of parathyroid cell resistance to 1,25(OH)<sub>2</sub>D-mediated suppression of SHPT has required the generation of synthetic 1,25(OH)<sub>2</sub>D analogs with an efficacy similar to that of 1,25(OH)<sub>2</sub>D to suppress PTH but with less calcemic and phosphatemic activity. Importantly, analog treatment conferred hemodialysis patients with a survival advantage over 1,25(OH)<sub>2</sub>D treatment through renal and cardiovascular protective actions not fully accounted for by their efficacy in reducing circulating PTH [8]. (2) Vitamin D deficiency is highly prevalent in CKD patients [9] and associated with a mortality risk higher than that of 1,25(OH)<sub>2</sub>D deficiency [10,11], highlighting an unprecedented role for the kidney in maintaining circulating levels of the 1,25(OH)<sub>2</sub>D precursor 25-hydroxyvitamin D (25(OH)D) and facilitating continued extra-renal 1,25(OH)<sub>2</sub>D synthesis [1]. These findings led to an update in the 2017 KDIGO guidelines to normalize serum 25(OH)D in CKD patients prior to

the initiation of 1,25(OH)<sub>2</sub>D (analog) therapy for SHPT. (3) 1,25(OH)<sub>2</sub>D induces expression of the phosphaturic hormone FGF23 [12] and of the longevity gene  $\alpha$ -klotho [13] to maintain the functional integrity of the FGF23-klotho/1,25(OH)<sub>2</sub>D/phosphate axis, which suppresses PTH and protects against the renal and cardiovascular pro-aging effects of hyper-phosphatemia and hypervitaminosis D and maintains the anti-aging, pro-survival benefits of renal and circulating klotho. However, in CKD, 1,25(OH)<sub>2</sub>D (analog) therapy for secondary hyperparathyroidism (SHPT) may further exacerbate hyperphosphatemia and the increases in serum FGF23, which together with the progressive reductions in renal klotho from early CKD2 generate resistance to FGF23 phosphaturic and PTH suppressive actions. Significantly, high FGF23 exerts a klotho-independent induction of left ventricular hypertrophy (LVH) worsening the risk of cardiovascular mortality [14]. Thus, therapeutic strategies with calcimimetic drugs, which control secondary hyperparathyroidism with attenuated increases in FGF23, have challenged the efficacy of 1,25(OH)<sub>2</sub>D suppression of PTH in reducing cardiovascular risk. However, the recent discoveries of CKD-induced increases in FGF23 unrelated to 1,25(OH)<sub>2</sub>D therapy (reviewed in Refs. [15,16]) as well as of 1,25(OH)<sub>2</sub>D induction of FGF23/soluble klotho/FGFR1 ternary complexes to antagonize FGF23 pathological actions [17] demand a re-examination of current recommendations for vitamin D interventions in CKD. The link between vitamin D and FGF23 is discussed further in Chapter 19.

This chapter updates the progress in our understanding of the molecular pathophysiology underlying CKD-induced disturbances in systemic and tissue-specific vitamin D metabolism and actions that accelerate the onset and progression of SHPT and of skeletal, immune, renal, and cardiovascular aging and compromise survival. This knowledge should help identify tissue-specific targets for 1,25(OH)<sub>2</sub>D/analog pro-survival actions to facilitate the development of vitamin D interventions that safely prevent the onset of CKD or attenuate its progression to end-stage renal disease. Related chapters in this book include Chapter 26 (vol. 1), Chapter 47 (vol. 1) and Chapter 80 (vol. 2).

## 2. Renal regulation of the vitamin D endocrine system

The integrity of the vitamin D endocrine system plays a central role in the tight control of complex calcium and phosphate fluxes, as well as the secretory control and hormonal interactions among the kidney, the parathyroid glands, bone, and intestine [18]. Normal renal synthesis and secretion of the potent calcitropic hormone 1,25(OH)<sub>2</sub>D [19] are critical to integrate the calcium/PTH axis as well as the phosphorus/FGF23-klotho loop

that ensures normal calcium and phosphorus homeostasis and skeletal integrity [20]. These loops are essential in preventing an excess of calcium and phosphate ions that could lead to over-mineralization of bone, ectopic calcification, and also renal and cardiovascular aging driven by hyperphosphatemia, high FGF23, and renal klotho reductions (reviewed in Ref. [21]) and depicted in Fig. 79.1.

Briefly, in normal individuals, a decrease in serum calcium is sensed by the parathyroid gland, which rapidly enhances the secretion and/or synthesis of PTH to restore calcium balance. Elevations in serum PTH induce calcium resorption from bone and stimulate the expression and activity of renal CYP27B1, also called 25-hydroxyvitamin D 1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase), the enzyme responsible for the conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D. The increases in serum 1,25(OH)<sub>2</sub>D induce intestinal calcium absorption, renal reabsorption, and bone resorption if dietary calcium is insufficient. Upon normalization of calcium levels, both calcium and 1,25(OH)<sub>2</sub>D close the loop by suppressing PTH synthesis and, in the case of 1,25(OH)<sub>2</sub>D, also through a tight regulation of its own circulating levels by suppressing renal 1 $\alpha$ -hydroxylase expression and activity and by inducing its own catabolism by renal CYP24A1 (24-hydroxylase) to avoid the toxicity associated to hypervitaminosis D [19].

1,25(OH)<sub>2</sub>D also elevates serum phosphorus levels by promoting intestinal absorption, renal reabsorption, and bone resorption, increases that promote vascular calcification in a PTH-independent manner [22]. Both high phosphorus and 1,25(OH)<sub>2</sub>D, the latter only in the presence of hyperphosphatemia and a certain calcium threshold [23], induce FGF23 stabilization [24] and synthesis in bone, respectively [12,15]. In the normal kidney, a highly coordinated regulation of renal CYP27B1 and CYP24A1 expression and activity by serum 1,25(OH)<sub>2</sub>D, PTH, FGF23, calcium, and phosphate ensures the functional integrity of skeletal and mineral homeostasis [25].

1,25(OH)<sub>2</sub>D also induces the renal expression of the longevity/antiaging klotho molecule, whose transmembrane and soluble forms are critical for the proper functioning of the phosphorus/1,25(OH)<sub>2</sub>D/FGF23–klotho loop required for the prevention of hyperphosphatemia and hyper-vitaminosis D-induced skeletal, renal, and cardiovascular aging [26]. Specifically, the FGF23/klotho loop exerts a direct inhibition of 1 $\alpha$ -hydroxylase expression, induces CYP24A1, the enzyme responsible for 1,25(OH)<sub>2</sub>D degradation, and also lowers serum phosphorus, through the inhibition of both renal phosphate reabsorption [27,28] and PTH secretion, thereby attenuating bone resorption and the risk of vascular calcification. Circulating klotho not only acts as a co-receptor for FGF23 signaling but also exerts skeletal, renal, and cardiovascular protection in an FGF23-independent manner [29].

In CKD, a defective maintenance of circulating 25(OH)D by the injured kidney aggravates the

progressive loss of the renal capacity to synthesize 1,25(OH)<sub>2</sub>D. The combined vitamin D and 1,25(OH)<sub>2</sub>D deficiency exacerbates the early reductions in circulating klotho, severely compromising the functional integrity of the PTH/1,25(OH)<sub>2</sub>D/calcium and FGF23-klotho/1,25(OH)<sub>2</sub>D/phosphate axes. Appropriate regulation of these axes is essential to control SHPT, to counteract the skeletal, renal, and cardiovascular aging driven by hyperphosphatemia and to protect from excessive FGF23-driven LVH.

The following section updates our understanding of (1) the pathogenic mechanisms impairing the ability of the injured kidney to maintain serum 25(OH)D levels and appropriate renal or extra-renal 1,25(OH)<sub>2</sub>D production and (2) the adverse impact of the abnormalities in renal and extra-renal vitamin D metabolism in response to vitamin D supplementation, 25(OH)D administration or 1,25(OH)<sub>2</sub>D (analogs) replacement therapy. This information is essential to resolve current controversies in the appropriate management of vitamin D and 1,25(OH)<sub>2</sub>D deficiency in CKD to improve renal and cardiovascular outcomes.

### 3. Alterations in vitamin D bioactivation to 25(OH)D in chronic kidney disease

Vitamin D is not a vitamin, as “vitamin” is the name for compounds that our body cannot produce and, in mammals, vitamin D is produced by the skin (see Chapter 3). As summarized in Fig. 79.2 [18], skin exposure to sunlight of the ultraviolet B range (UV-B) converts 7-dehydrocholesterol into vitamin D<sub>3</sub> (cholecalciferol) [18], a conversion attenuated by sun blockers [30]. CKD impairs this photo-activation of the vitamin D precursor by the skin [31]. Large genome-wide association studies (GWASs) in white Europeans have identified polymorphisms in 7-dehydrocholesterol reductase (DHCR7, the enzyme that converts 7-dehydrocholesterol into cholesterol) that are associated with reduced vitamin D levels [32], likely due to DHCR7 removal of the substrate for vitamin D synthesis. In a European cohort of 500 CKD children, vitamin D deficiency was prevalent in two-thirds of the cohort [33] but was not independently associated with these polymorphisms. However, the abnormal cholesterol metabolism in CKD suggests that skin DHCR7 may play a larger role in the regulation of vitamin D status than previously recognized.

Vitamin D<sub>3</sub> and its homolog in plants, vitamin D<sub>2</sub> (ergocalciferol), are inactive prohormones, which need to undergo a two-step bio-activation to the potent calcitropic steroid hormone 1,25(OH)<sub>2</sub>D<sub>2</sub> or D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>) to exert their biological actions (see Chapter 4). In the first activation step, vitamin D<sub>3</sub> undergoes 25-hydroxylation mainly in the liver by two cytochromes

**FIGURE 79.2 Systemic and parathyroid vitamin D metabolism and actions.** Two hydroxylation steps, 25-hydroxylation in the liver and  $1\alpha$ -hydroxylation in the kidney, convert inactive vitamin D produced in the skin by exposure to UV light, into the potent calcitropic hormone  $1,25(\text{OH})_2\text{D}$ . The kidney tightly controls serum  $1,25(\text{OH})_2\text{D}$  by inducing its degradation by CYP24A1 when serum levels raise above normal. Parathyroid cells express all the cytochromes P450 required for  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  production and for their metabolic inactivation. The cells also express megalin, an endocytosis receptor required for the cellular uptake of  $25(\text{OH})\text{D}$ , which circulates bound to its carrier, DBP. Once inside the parathyroid cell, the degree of  $1,25(\text{OH})_2\text{D}$ -VDR complex formation, required to induce the transcription of the genes that control secondary hyperparathyroidism (SHPT), will depend on the net balance between stimuli for  $1,25(\text{OH})_2\text{D}$  activation versus degradation. Note the opposite regulation by FGF23 of  $1,25(\text{OH})_2\text{D}$  production by CYP27B1 in the kidney and in parathyroid cells.  $1,25(\text{OH})_2\text{D}$  is the most potent inducer of VDR activation (the widest arrow) and transcriptional regulation of vitamin D-responsive genes. However,  $25(\text{OH})\text{D}$  also binds and activates the VDR with a 100–200 lower potency (a narrower arrow). Importantly,  $25(\text{OH})\text{D}$  can synergize with  $1,25(\text{OH})_2\text{D}$  activation of the VDR (+). An autocrine/paracrine induction of the  $25(\text{OH})\text{D}$ – $1,25(\text{OH})_2\text{D}$  synergy for VDR activation should maximize the biological response to VDR activation with a minimal risk of hypercalcemia or hyperphosphatemia. FGF23, fibroblast growth factor 23; VDR, vitamin D receptor.

P450s, mitochondrial CYP27A1, and microsomal CYP2R1. CYP27A1, an enzyme whose inactivating mutation causes abnormal cholesterol and bile metabolism, but not rickets, cannot hydroxylate vitamin  $\text{D}_2$  [34]. In humans, CYP2R1 appears to be the most critical vitamin D-25-hydroxylase because mutations in this gene but not the CYP27A1 gene results in severe vitamin D deficiency (serum  $25(\text{OH})\text{D}$  levels below 10 ng/mL) [35] (see Chapter 67). Interestingly, simultaneous ablation of the CYP27A1 and CYP2R1 genes only reduced circulating  $25(\text{OH})\text{D}$  levels by 50%, thus suggesting an important contribution of other 25-hydroxylases [36]. CYP3A4, a major drug-metabolizing enzyme mainly located in the liver and intestine, also has 25-

hydroxylating activity but prefers  $1\alpha$ -hydroxylated substrates [37]. In addition to the liver, skin and parathyroid cells, as well as monocyte/macrophages, express 25-hydroxylase activity, but the impact on cellular function or on serum  $25(\text{OH})\text{D}$  levels has not been explored [38–40].

The vitamin D status of an individual is estimated by measurements of serum  $25(\text{OH})\text{D}$  because serum  $25(\text{OH})\text{D}$  levels accurately reflect the efficacy of hepatic 25-hydroxylases to convert most circulating vitamin D into  $25(\text{OH})\text{D}$  [41]. Also, the 15 to 18 day biological half-life of  $25(\text{OH})\text{D}$  prevents an underestimation of vitamin D status due to rapid fluctuations of serum  $25(\text{OH})\text{D}$  levels. Currently, only mass spectrometry

accurately measures 25(OH)D levels (see Chapter 50 [Vol. 1 of this book]). Chapter 49 (Vol. 1 of this book) discusses the accuracy and specificity of available assays.

CKD-induced changes in the expression or activity of the hepatic or extra-hepatic 25-hydroxylase may contribute to the high variability in the response of these patients to ergocalciferol or cholecalciferol supplementation. However, the high degree of vitamin D deficiency in CKD is not caused by a defective conversion of vitamin D into 25-hydroxyvitamin D but mainly by progressive reductions in renal megalin. Severe vitamin D deficiency was noted in megalin-null mice, uncovering a previously unrecognized role for a normal kidney in the maintenance of normal serum 25(OH)D [42]. This role involves the uptake of 25(OH)D from the urinary ultra-filtrate and its recycling back to the circulation, summarized in Fig. 79.3. Briefly, 25(OH)D, a lipid soluble molecule, circulates in the blood mostly bound to its carrier, the vitamin D-binding protein (DBP), with a molecular weight similar to that of albumin, another carrier of vitamin D metabolites with lower binding affinity than DBP. The 25(OH)D/DBP or 25(OH)D/albumin complex is filtered through the glomerulus and reenters proximal tubular cells through a process of endocytosis that requires adequate tubular levels of the endocytosis receptor megalin, a member of the low-density lipoprotein (LDL) receptor superfamily. Chapter 7 provides a more detailed discussion of DBP.

In CKD, an early loss of renal megalin is evident in rats after only 2 weeks of the induction of renal injury [43]. Thus, defective renal 25(OH)D uptake provides a mechanistic explanation for the high incidence of vitamin D deficiency at all CKD stages [9]. Supplementation with ergocalciferol, cholecalciferol, or 25(OH)D increases the proportion of DBP carrying 25(OH)D in the blood and the amount of filtered 25(OH)D/DBP complex available for megalin-mediated endocytosis, regardless of a normal or reduced glomerular filtration rate (GFR). Undoubtedly, in CKD, progressive reductions in megalin and in GFR contribute to the difficulties in normalizing serum 25(OH)D levels in response to vitamin D supplementation [44,45].

Because vitamin D induces the expression of renal megalin [46], the correction of vitamin D deficiency at early CKD stages could attenuate renal megalin loss. In predialysis CKD patients, urinary megalin excretion correlates directly with urinary protein and inversely with circulating 25(OH)D levels. Thus, measurements of urinary megalin in CKD could provide an early biomarker of the degree of renal proximal tubular cell injury [47] to help personalize vitamin D supplementation strategies.

The question remains as to what is the optimal serum 25(OH)D level or vitamin D supplementation regimen in CKD? A Japanese study in a large population of predialysis patients with CKD3–5, demonstrated that serum levels of 25(OH)D above 23 ng/mL significantly

**FIGURE 79.3** Defective renal 25(OH)D uptake limits renal calcitriol synthesis in CKD. Left panel: Circulating 25(OH)D (25D) bound to its carrier vitamin D-binding protein (DBP) is filtered by the kidney and internalized into proximal tubular cells via megalin-mediated endocytosis. On its release from DBP, 25(OH)D is either delivered to  $1\alpha$ -hydroxylase by intracellular vitamin D-binding protein 3 (IDBP3) for its bioactivation to 1,25(OH)<sub>2</sub>D (1,25D), or it reenters the circulation. Calcitriol induces renal megalin expression, thereby generating a cycle that ensures normal systemic 25(OH)D and calcitriol levels as well as the reabsorption of low-molecular-weight proteins from the glomerular filtrate, including albumin. In CKD, decreases in GFR and low megalin content contribute to impair 25(OH)D uptake and protein reabsorption. Right panel: The strong correlation between serum levels of 25(OH)D and calcitriol [1,25(OH)<sub>2</sub>D] in hemodialysis patients (GFR < 25 mL/min), which is absent in normal individuals (dotted line), demonstrates impaired 25(OH)D availability for its bioactivation to calcitriol by the remnant renal  $1\alpha$ -hydroxylase in CKD. Only supraphysiological concentrations of 25(OH)D normalize serum calcitriol levels. CKD, chronic kidney disease; VDR, vitamin D receptor. Adapted from Ref. [89].

reduced the risk of CKD progression [11]. Notably, this 25(OH)D concentration was shown insufficient to reduce PTH in adult CKD. In children with CKD2–4, supplementation with ergocalciferol (2000 units IU daily) was sufficient to delay the onset of SHPT [48] and to lower serum PTH. A recent meta-analysis of four-randomized controlled trials in pre-dialysis and hemodialysis patients supported these findings [49]. However, in adult patients with CKD stages 3–4, daily administration of 4000 IU of cholecalciferol for 1 month followed by 2000 IU daily for 2 additional months increased serum 25(OH)D levels from 14 to 37 ng/mL without reducing PTH [44]. In a similar cohort of patients, ergocalciferol administration (50,000 IU, every 2 weeks) effectively reduced serum PTH only in 50% of the patients achieving serum 25(OH)D levels above 35 ng/mL [50]. Instead, daily doses of 8000 IU of cholecalciferol for 12 weeks significantly reduced PTH without hypercalcemia or hyperphosphatemia [51], suggesting that high daily doses of cholecalciferol may represent a superior supplementation regimen. While the optimal vitamin D replacement regimen in individuals with CKD remains unclear, it is well recognized that vitamin D supplementation regimens will depend on the CKD stage and should be personalized to improve outcomes rather than to normalize serum 25(OH)D levels. Significantly, a typical U-shaped curve for the association between serum 25(OH)D and relative risk of mortality in healthy women [52] underscores the importance of avoiding an excess of serum 25(OH)D. Therefore, a better understanding of CKD-induced abnormalities of renal and extra-renal 1,25(OH)<sub>2</sub>D synthesis and of 25(OH)D and 1,25(OH)<sub>2</sub>D catabolism is required (to be discussed in the following).

#### 4. Alterations in renal 1,25(OH)<sub>2</sub>D synthesis and 25(OH)D and 1,25(OH)<sub>2</sub>D catabolism in chronic kidney disease

The 1 $\alpha$ -hydroxylation of 25(OH)D to produce 1,25(OH)<sub>2</sub>D, the most active endogenous vitamin D metabolite, is the most critical and tightly regulated of the two steps in vitamin D bio-activation. This step is catalyzed by the mitochondrial cytochrome P450 mixed-function oxidase CYP27B1 or 1 $\alpha$ -hydroxylase [19] and occurs mainly, but not exclusively, in the renal proximal convoluted tubules (see Chapter 8 [Vol. 1 of this book]). Indeed, the kidney is the main, if not the only, contributor to circulating 1,25(OH)<sub>2</sub>D, at least under physiological conditions. Therefore, for more than 3 decades, nephrologists have used oral or intravenous 1,25(OH)<sub>2</sub>D/analogues to correct the progressive reductions in renal 1,25(OH)<sub>2</sub>D production when GFRs fall below 50% of normal [53–56].

Serum 1,25(OH)<sub>2</sub>D levels should be maintained within the narrow limits that ensure the functional integrity of the calcium/1,25(OH)<sub>2</sub>D/PTH and phosphorus/1,25(OH)<sub>2</sub>D/FGF23–klotho axes controlling bone and mineral homeostasis with minimal risk of renal or cardiovascular injury due to hypercalcemia or hyperphosphatemia. Therefore, renal 1,25(OH)<sub>2</sub>D production is strictly controlled through a tight and coordinated regulation of 1,25(OH)<sub>2</sub>D synthesis by 1 $\alpha$ -hydroxylase and of 1,25(OH)<sub>2</sub>D catabolism by CYP24A1 or 24-hydroxylase, the cytochrome P450 that catalyzes 25(OH)D and 1,25(OH)<sub>2</sub>D metabolic inactivation [18]. Indeed, in normal individuals, when 1,25(OH)<sub>2</sub>D production rate increases above normal levels, the metabolic clearance rate of 1,25(OH)<sub>2</sub>D is accelerated [57]. Accordingly, severe hypercalcemia and nephrocalcinosis develop in children and adults with a loss-of-function mutation of the 24-hydroxylase gene [58,59] (see Chapter 69). These pathological features mimic the phenotype of high serum 1,25(OH)<sub>2</sub>D, severe hypercalcemia, hyperphosphatemia, osteoporosis, nephrocalcinosis, and vascular calcification in the 24-hydroxylase null mouse [60].

1 $\alpha$ -hydroxylase and 24-hydroxylase expression and activity are tightly regulated by the three mineralotropic hormones PTH, FGF23, and 1,25(OH)<sub>2</sub>D and also by the main modulators of their circulating levels, serum calcium, and phosphate. PTH, hypocalcemia, and hypophosphatemia are the major CYP27B1 inducers, while FGF23, klotho, hyperphosphatemia, hypercalcemia, and 1,25(OH)<sub>2</sub>D are the main repressors. Conversely, CYP24A1 is induced by 1,25(OH)<sub>2</sub>D and FGF23 and inhibited by PTH (reviewed in Ref. [19]).

In health, PTH is the most potent stimulator of renal 1,25(OH)<sub>2</sub>D synthesis (see Chapter 8). Patients with hypoparathyroidism have low 1,25(OH)<sub>2</sub>D levels despite persistent hypocalcemia [61] and parathyroidectomy severely blunt the induction of renal 1 $\alpha$ -hydroxylase by hypocalcemia [62]. Dietary phosphate restriction also increases renal 1,25(OH)<sub>2</sub>D production, serum 1,25(OH)<sub>2</sub>D, and mRNA levels of renal 1 $\alpha$ -hydroxylase [63,64] despite decreases in serum PTH [65]. Growth hormone may play a role in low phosphorus-driven induction of renal-1 $\alpha$ -hydroxylase mRNA levels and serum 1,25(OH)<sub>2</sub>D, as hypophysectomy blocks, whereas injection of growth hormone or IGF1 to hypophysectomized rats restores renal 1,25(OH)<sub>2</sub>D production [66].

FGF23 and klotho strongly suppress renal CYP27B1 mRNA levels and 1,25(OH)<sub>2</sub>D synthesis, as conclusively demonstrated by the high basal CYP27B1 mRNA levels and high serum 1,25(OH)<sub>2</sub>D in the FGF23 and klotho-null mice despite severe hypercalcemia, hyperphosphatemia, and low PTH [67] and also despite the high FGF23 in the klotho-null mice [68] (see Chapter 19). The latter supports either a key role for the FGF23/membrane or

soluble klotho complex to suppress 1 $\alpha$ -hydroxylase in an intact kidney, as suggested by the proximal tubule specific klotho ablation [69], or an FGF23-independent suppression of 1 $\alpha$ -hydroxylase by  $\alpha$ -klotho.

1,25(OH)<sub>2</sub>D feedback inhibits 1 $\alpha$ -hydroxylase activity [70,71] and gene expression [72–75], the latter not through classical VDR-trans-repression but through the suppression of the PTH/cAMP induction of 1 $\alpha$ -hydroxylase gene expression [76], and induces renal CYP24A1 gene transcription through VDR binding to the two proximal VDREs on the CYP24A1 gene promoter [77]. Several indirect mechanisms also contribute to 1,25(OH)<sub>2</sub>D inhibition of net renal 1,25(OH)<sub>2</sub>D production in vivo, including 1,25(OH)<sub>2</sub>D-mediated increases in serum calcium and phosphorus levels, suppression of serum PTH, and induction of FGF23 [12,21] and renal klotho [67], all of which also induce 24-hydroxylase.

The most critical advances in our understanding of the coordinated regulation of renal 1,25(OH)<sub>2</sub>D synthesis and catabolism by PTH, FGF23, and 1,25(OH)<sub>2</sub>D in health came from very recent work from the Pike laboratory reviewed in Ref. [78]. Using complex genomic approaches and loss-of-function studies, they identified CYP27B1 gene regulatory modules that are highly specific for renal proximal tubular cells and the sole determinants of 1 $\alpha$ -hydroxylase responses to PTH, FGF23, and 1,25(OH)<sub>2</sub>D [25]. These four submodules are dispersed and located within specific introns in the adjacent *Mettl1* and *Mettl21b* genes. While the submodules in *Mettl1* control PTH induction of the 1-hydroxylase gene, three separate submodules in the *Mettl21b* gene mediate FGF23 inhibition, and all four modules are involved in its suppression by 1,25(OH)<sub>2</sub>D [25].

The high translational relevance of these novel CYP27B1 regulatory modules resides in the demonstration that specific deletion of the PTH-responsive module in mice is sufficient to cause a 99% reduction in 1 $\alpha$ -hydroxylase gene expression and a bone and mineral phenotype similar to that of the *Cyp27b1* null mice, with marked decreases in circulating 1,25(OH)<sub>2</sub>D (absent in the *Cyp27b1* null mice) and in intestinal calcium absorption, leading to elevations in circulating PTH, reductions in FGF23, and renal *Cyp24a1* gene expression, as well as decreased bone mass. Proof of the coordinated renal regulation of *Cyp27b1* and *Cyp24a1* was found when rescuing these mouse models with high-calcium and high-phosphorus diets, which raised serum calcium, phosphate, and FGF23 levels; suppressed PTH; and normalized *Cyp24a1* expression, resulting in undetectable 1,25(OH)<sub>2</sub>D levels. As these modules are not present in non-renal cells expressing 1 $\alpha$ -hydroxylase, these findings also ruled out the potential contribution of non-renal sources of 1,25(OH)<sub>2</sub>D to the very low but detectable circulating levels of 1,25(OH)<sub>2</sub>D upon

ablation of the 1 $\alpha$ -hydroxylase regulating modules, at least in mice with normal kidneys (see Chapter 8).

In addition, Pike and collaborators have identified another exclusive renal module, which mediates the opposing regulation of *Cyp24a1* by PTH and FGF23, and which is associated with the disappearance of remnant 1,25(OH)<sub>2</sub>D upon dietary normalization of PTH and FGF23 in mice with an ablated PTH-responsive module for *Cyp27b1*. It is comprised of one segment located inter-genically downstream from the *Cyp24a1* transcriptional start site. Importantly, mice with exclusive deletion of the PTH responsive module controlling *Cyp27b1* expression also had higher serum 25(OH)D than wild-type mice, which normalized after feeding with the high-calcium, high-phosphorus rescue diet that induced FGF23 and *Cyp24a1* expression. This corroborates the importance of the coordinated regulation of 1 $\alpha$ -hydroxylase and 24-hydroxylase expression and activity by PTH and FGF23 by a normal kidney to prevent elevations in circulating 25(OH)D above normal [78]. Significantly, a second module that controls *Cyp24a1* transactivation by 1,25(OH)<sub>2</sub>D was identified exclusively in non-renal VDR-responsive cells but not in renal cells [78]. This underscores the distinct transactivation of the renal-constitutively expressed and non-renal-inducible *Cyp24a1* by 1,25(OH)<sub>2</sub>D.

At present, it is unknown at what point in the course of CKD progression, this highly inter-coordinated transcriptional regulation of *Cyp27b1* and *Cyp24a1* expression by 1,25(OH)<sub>2</sub>D, PTH, and FGF23 is lost. CKD also impairs the response to the classical regulators of renal 1,25(OH)<sub>2</sub>D synthesis. The accumulation of N-terminally truncated PTH fragments or C-terminal PTH, known to directly inhibit renal 1 $\alpha$ -hydroxylase [79], could partly account for the reduced 1,25(OH)<sub>2</sub>D production in response to either calcium restriction [80] or high serum PTH [81]. Phosphorus restriction in patients with end-stage renal disease [82] or in severely uremic dogs [83] failed to increase serum 1,25(OH)<sub>2</sub>D. The accumulation of uremic toxins also reduces renal 1,25(OH)<sub>2</sub>D synthesis, as shown by the infusion of uremic plasma ultra-filtrate into normal rats and the potent inhibition of 1 $\alpha$ -hydroxylase activity in vitro by low-molecular-weight compounds from uremic plasma ultra-filtrate [84]. Accordingly, in partially nephrectomized rats, increases in dietary protein intake that induce the production of uremic toxins markedly suppress 1,25(OH)<sub>2</sub>D synthesis.

Significantly, the abnormal regulation of 1 $\alpha$ -hydroxylase expression and activity in proximal tubules in CKD is not the only determinant of the progressive decreases in circulating 1,25(OH)<sub>2</sub>D levels. In fact, in early studies in hemodialysis patients with a GFR below 25 mL/min, accompanied by severely limited renal-1 $\alpha$ -hydroxylase activity and likely very high serum FGF23, serum

1,25(OH)<sub>2</sub>D levels were low only if serum 25(OH)D concentrations were low or normal [85]. Importantly, serum levels of 1,25(OH)<sub>2</sub>D could be normalized in these patients simply by increasing the serum concentrations of 25(OH)D to 100–200 ng/mL through oral supplementation. Furthermore, a strong correlation exists between serum levels of 25(OH)D and 1,25(OH)<sub>2</sub>D that does not occur in individuals with normal kidney function (see Fig. 79.3, right panel). A more recent prospective study corroborated the progressive increases in 1,25(OH)<sub>2</sub>D in vitamin D–deficient hemodialysis patients treated with 25(OH)D for 6 months [86]. Kinetic studies in dogs with moderate or severe uremia demonstrated that the increases in serum 1,25(OH)<sub>2</sub>D in response to 25(OH)D supplementation involved increases in production rates [87], thus supporting the importance of the maintenance of serum 25(OH)D levels for 1,25(OH)<sub>2</sub>D production by the remnant renal enzyme even in end-stage renal disease.

Even though the strong correlation between serum 25(OH)D and 1,25(OH)<sub>2</sub>D may result from impaired 25(OH)D availability for renal 1 $\alpha$ -hydroxylase described before [85] and caused partially by megalin reductions [43], it is also possible that the high serum 25(OH)D competes with the low 1,25(OH)<sub>2</sub>D as the substrate for Cyp24a1, thereby increasing serum 1,25(OH)<sub>2</sub>D by reducing its catabolism. However, the contribution of extra-renal 1,25(OH)<sub>2</sub>D production to the observed elevations in serum 1,25(OH)<sub>2</sub>D after 25(OH)D administration in advanced CKD should not be ruled out, as will be discussed in the following.

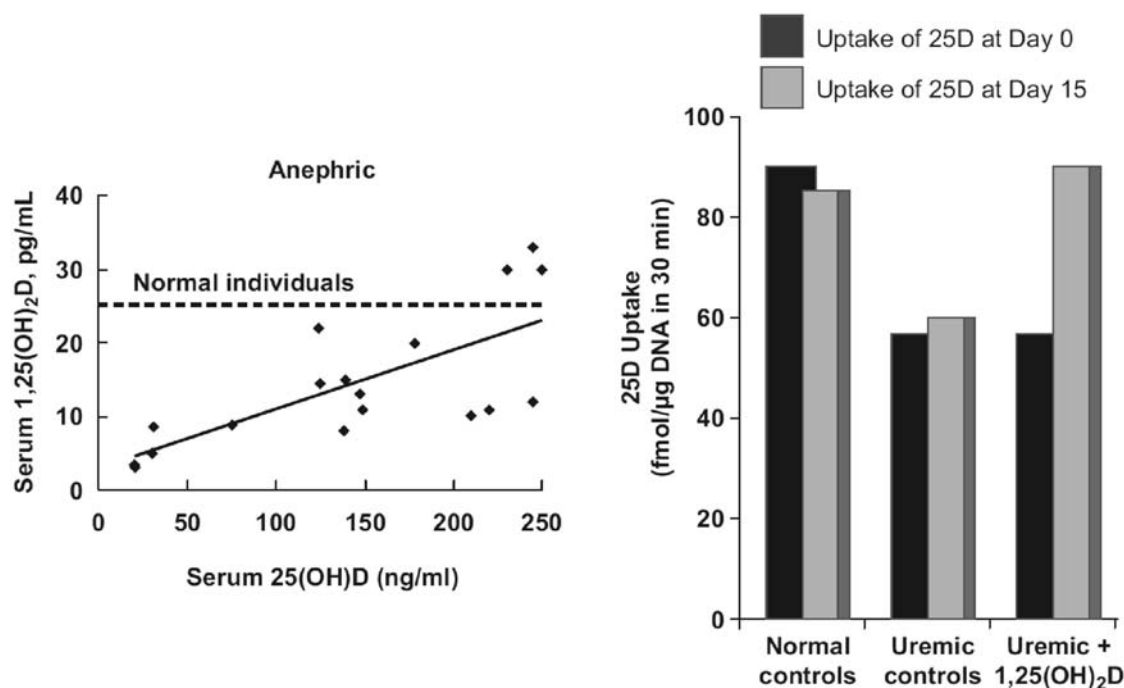

CKD may also impair substrate availability for 25(OH)D catabolism. In experimental and human CKD, despite marked elevations in renal 24-hydroxylase mRNA levels induced by the high FGF23, serum levels of 24,25-dihydroxyvitamin D, a biomarker of Cyp24a1 activity, are low rather than elevated [88,89]. These findings have corroborated the early work by Ishimura and colleagues in rats overexpressing renal Cyp24a1 [90]. More importantly, low serum 24,25-dihydroxyvitamin D levels in these transgenic rats were not caused by accelerated degradation of vitamin D metabolites. Instead, an impaired renal uptake of 25(OH)D due to albuminuria prevented its degradation by the overexpressed 24-hydroxylase [90]. Therefore, CKD impairs the response to FGF23 induction of 24-hydroxylase to avoid vitamin D toxicity, possibly through the same reductions in renal megalin compromising 25(OH)D uptake for 1,25(OH)<sub>2</sub>D synthesis. A recent prospective trial on ergocalciferol supplementation at earlier CKD stages corroborated a reduction in vitamin D catabolism, as measured by 24,25(OH)<sub>2</sub>D/25(OH)D ratios. This reduction occurred despite unchanged serum PTH, FGF23, DBP, or albumin levels and was attributed to defective substrate availability

[91]. Taken together, these findings indicate that progressive impairments in 25(OH)D and 1,25(OH)<sub>2</sub>D catabolism in the course of CKD render these patients more sensitive to vitamin D toxicity than previously estimated. Undoubtedly, to comply with current KDIGO guidelines on vitamin D interventions, serial measurements of changes in vitamin D metabolite ratios (1,25(OH)<sub>2</sub>D/25(OH)D; 24,25(OH)<sub>2</sub>D/25(OH)D, and 1,25(OH)<sub>2</sub>D/24,25(OH)<sub>2</sub>D) with CKD progression would better reflect the degree of impaired control of renal 1,25(OH)<sub>2</sub>D synthesis and of 25(OH)D and 1,25(OH)<sub>2</sub>D catabolism in response to elevations in PTH and FGF23 than single measurements of serum 25(OH)D and 1,25(OH)<sub>2</sub>D levels.

### 5. Alterations in 1,25(OH)<sub>2</sub>D production by extrarenal 1 $\alpha$ -Hydroxylases in chronic kidney disease

In CKD, non-renal 1 $\alpha$ -hydroxylases contribute to systemic 1,25(OH)<sub>2</sub>D levels, as conclusively demonstrated in bilaterally nephrectomized patients undergoing hemodialysis [92]. Furthermore, there is a strong correlation between serum levels of 25(OH)D and 1,25(OH)<sub>2</sub>D depicted in Fig. 79.4 (left panel) suggesting that CKD also impairs 25(OH)D availability to non-renal 1 $\alpha$ -hydroxylases. In fact, in the absence of renal mass, the very low serum 1,25(OH)<sub>2</sub>D levels can be raised to normal levels with appropriate 25(OH)D supplementation [92]. This early work also supports the contribution of extra-renal 1,25(OH)<sub>2</sub>D synthesis to the increases in serum 1,25(OH)<sub>2</sub>D observed in hemodialysis patients on 25(OH)D [92] or cholecalciferol supplementation [93].

The impact of CKD on 1,25(OH)<sub>2</sub>D production by non-renal 1 $\alpha$ -hydroxylases was first examined in monocyte/macrophages, as the enzyme is identical to the renal 1 $\alpha$ -hydroxylase though more readily accessible. Surprisingly, monocytes derived from peripheral blood mononuclear cells from hemodialysis patients had a higher expression of 1 $\alpha$ -hydroxylase than monocytes from normal individuals [94]. This suggests a role for the 1 $\alpha$ -hydroxylase of monocytes in compensating for the defective 1,25(OH)<sub>2</sub>D production by the proximal tubule cells of an injured kidney. The higher monocyte 1 $\alpha$ -hydroxylase activity appears to reflect a defective feedback inhibition of the enzyme expression/activity by the low serum 1,25(OH)<sub>2</sub>D levels, as monocytes lack PTH receptors, and monocyte 1 $\alpha$ -hydroxylase does not respond to changes in serum calcium and phosphorus levels as the renal enzyme does [94]. However, monocyte 1 $\alpha$ -hydroxylase is also inhibited by high serum FGF23 [95]. In fact, the V<sub>max</sub> of monocyte 1 $\alpha$ -hydroxylase, a measure of the cellular content of the

**FIGURE 79.4** 1,25(OH)<sub>2</sub>D corrects the impaired 25(OH)D availability to nonrenal 1 $\alpha$ -hydroxylase in CKD. Left panel: The strong correlation between serum levels of 25(OH)D and 1,25(OH)<sub>2</sub>D in bilaterally nephrectomized patients (anephrics) demonstrates impaired 25(OH)D availability for its bioactivation to 1,25(OH)<sub>2</sub>D by nonrenal 1 $\alpha$ -hydroxylase. Only supraphysiological concentrations of 25(OH)D normalize serum 1,25(OH)<sub>2</sub>D levels. Right panel: 25(OH)D uptake (30 min) at day 0 (left bar) and at day 15 (right bar) by peripheral blood monocytes from normal individuals (normal) and hemodialysis patients (uremic) receiving either vehicle (controls) or intravenous 1,25(OH)<sub>2</sub>D three times a week for 15 days. CKD, chronic kidney disease. Left panel: Adapted from Ref. [92]. Right panel: Modified from Ref. [96].

enzyme, correlates inversely with serum 1,25(OH)<sub>2</sub>D and is exquisitely sensitive to downregulation by physiological levels of 1,25(OH)<sub>2</sub>D [96].

The tight control of monocyte–macrophage 1,25(OH)<sub>2</sub>D synthesis by physiological concentrations of serum 1,25(OH)<sub>2</sub>D in CKD patients differs markedly with that reported in monocytes from patients with sarcoidosis and other granulomatous diseases. In these disorders, hypercalcemic episodes result from the inability of the high serum 1,25(OH)<sub>2</sub>D concentrations to either suppress 1,25(OH)<sub>2</sub>D synthesis by the disease-activated macrophages or to induce 24-hydroxylase [97].

The regulation of CYP27B1 in non-renal cells differs markedly from the response to the same modulators in renal tubular cells, as they lack the regulatory modules that mediate the renal responses to PTH, FGF23, and 1,25(OH)<sub>2</sub>D. Furthermore, there is a distinct and cell-specific response to the same modulator. For instance, the high circulating levels of FGF23, common in CKD patients, inhibit monocyte/macrophage 1,25(OH)<sub>2</sub>D production [95], but induce 1 $\alpha$ -hydroxylase mRNA levels in cells from normal parathyroid glands [98]. The distinct regulation of renal and parathyroid 1 $\alpha$ -hydroxylase by FGF23 and that of monocyte/macrophage 1 $\alpha$ -hydroxylase in patients with CKD compared with individuals with inflammatory disorders underscores the

complexity behind the design of effective vitamin D interventions that improve clinical outcomes by simultaneously correcting endocrine and autocrine/paracrine VDR actions in the most relevant target cells/tissues.

Interestingly, CKD also impairs monocyte 25(OH)D uptake [96], as shown in peripheral blood monocytes from hemodialysis patients with a 40% lower uptake of 25(OH)D compared with monocytes from normal individuals (Fig. 79.4, right panel) [96]. This defective uptake can be corrected by normalizing the low-serum 1,25(OH)<sub>2</sub>D levels of hemodialysis patients through intravenous 1,25(OH)<sub>2</sub>D administration for 15 days (Fig. 79.4, right panel) [96]. Monocytes do not express megalin; however, the time course for 25(OH)D uptake is not linear, as would be expected for the diffusion of a free lipophilic compound through the plasma membrane [96]. Since 1,25(OH)<sub>2</sub>D modulates LDL receptor expression and function in the human monocytic cell line HL60 [99,100], and megalin is a member of the LDL receptor superfamily, a similar LDL receptor regulation may partially account for 1,25(OH)<sub>2</sub>D correction of the impaired uptake of 25(OH)D by peripheral blood monocytes from hemodialysis patients.

In the parathyroid gland, a defective uptake of 25(OH)D by parathyroid cells due to megalin reductions [101] could aggravate the adverse impact of vitamin D

deficiency for the correction of PTH synthesis by locally produced  $1,25(\text{OH})_2\text{D}$  [102]. Distinct levels of parathyroid megalin may contribute to the high variability demonstrated for CKD patients' suppression of PTH in response to vitamin D supplementation despite normalization of serum  $25(\text{OH})\text{D}$ .

The benefits of local  $1,25(\text{OH})_2\text{D}$  production extend beyond the control of SHPT. In a cohort of 158 hemodialysis patients, cholecalciferol supplementation resulted in higher serum  $25(\text{OH})\text{D}$  levels and also in elevations in  $1,25(\text{OH})_2\text{D}$  and albumin. More importantly, cholecalciferol supplementation reduced serum calcium, phosphorus, PTH, brain natriuretic peptide, left ventricular mass index, and the dose requirement for erythropoietin stimulating agents and for  $1,25(\text{OH})_2\text{D}$  (analogs) [93]. Importantly, in hemodialysis patients, with variable degrees of residual renal function, with poor or nonexistent megalin-mediated uptake of  $25(\text{OH})\text{D}$  from the urinary space, the capacity to increase serum  $25(\text{OH})\text{D}$  levels for local  $1,25(\text{OH})_2\text{D}$  synthesis decreases in direct proportion to their advanced proteinuria [103]. However, local  $25(\text{OH})\text{D}$  synthesis by parathyroid cells or monocytes could help normalize intracellular  $25(\text{OH})\text{D}$  levels for  $1,25(\text{OH})_2\text{D}$  synthesis and the local benefits VDR activation without changes in serum  $25(\text{OH})\text{D}$  levels.

Monocyte  $1,25(\text{OH})_2\text{D}$  production in response to cholecalciferol supplementation has also been reported to be beneficial in reducing the degree of systemic inflammation, measured by serum levels of the pro-inflammatory cytokines  $\text{TNF}\alpha$ , IL-8, and IL-6 [104]. In individuals with normal renal function, the capacity of monocytes to synthesize  $1,25(\text{OH})_2\text{D}$  from  $25(\text{OH})\text{D}$  to induce the gene expression of the antimicrobial peptide cathelicidin has provided a molecular explanation for the efficacy of a normal vitamin D status in protecting from tuberculosis [105] (see Chapter 94 and Chapter 98). Indeed, peripheral blood mononuclear cells from vitamin D-deficient African Americans restore their capacity to produce adequate amounts of cathelicidin following vitamin D supplementation. Undoubtedly, vitamin D-mediated improvement of the anti-inflammatory and antibacterial capacity of circulating monocytes in CKD patients has a beneficial impact on survival, as shown by the association of low levels of cathelicidin with a higher risk of death from infectious disease in dialysis patients [106].

The recent COVID 19 pandemic has provided additional evidence of the importance of a normal vitamin D status to effectively counteract the potent cytokine storm driving multi-organ damage to reduce disease severity and mortality rates in infected individuals [107–109]. It has also corroborated the high variability in outcomes in response to cholecalciferol or  $25(\text{OH})\text{D}$  dosage and timing (daily, weekly, monthly), baseline

vitamin D levels, and also racial differences. Notably, in the African American population, the risk of a clinically significant infection with normal circulating levels of  $25(\text{OH})\text{D}$  in the 30–40 ng/mL range is 2.45 higher than for levels above 40 ng/mL [110].

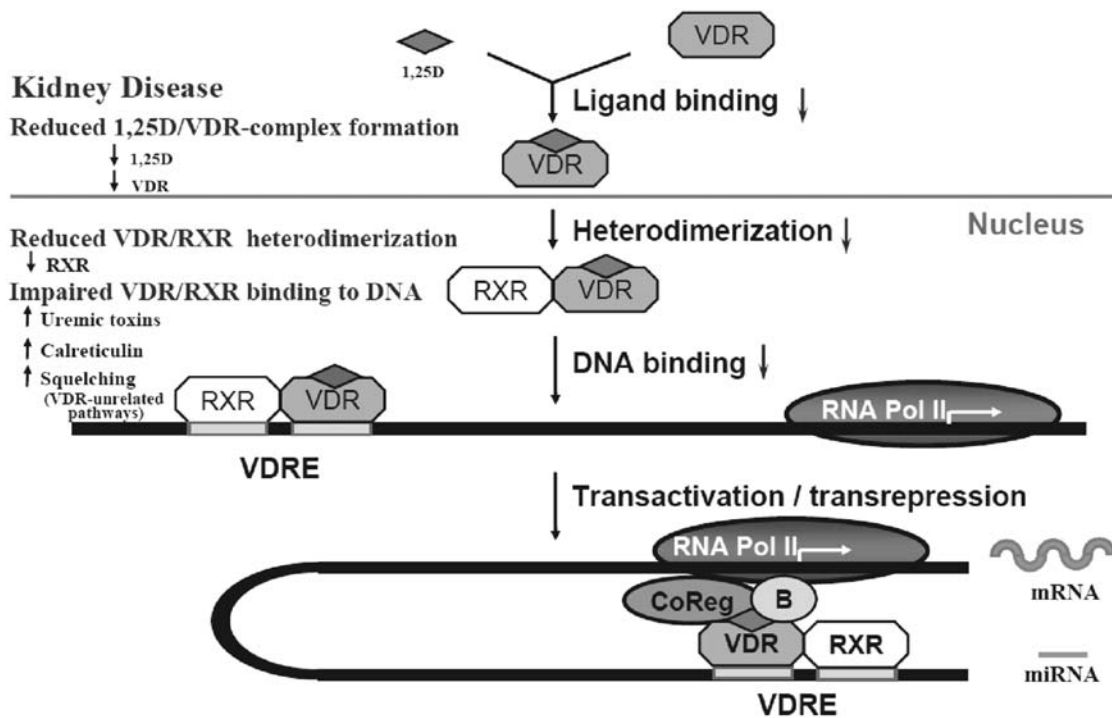

Although impaired uptake of circulating  $25(\text{OH})\text{D}$  in CKD patients may limit achieving full responses with vitamin D supplementation, it is certain that exclusive therapy with  $1,25(\text{OH})_2\text{D}$  (or analogs) will not correct vitamin D deficiency, thus fully preventing the reported benefits of autocrine/paracrine  $1,25(\text{OH})_2\text{D}$  production. Accordingly, current clinical guidelines recommend supplementation with nutritional vitamin D, mainly cholecalciferol, to correct vitamin D deficiency at all CKD stages before any intervention with  $1,25(\text{OH})_2\text{D}$  or its analogs (referred to as active vitamin D molecules) [111].

In summary, in the course of kidney disease, progressive reductions in serum  $25(\text{OH})\text{D}$  levels are key determinants of the severity of the defects in renal and extra-renal  $1,25(\text{OH})_2\text{D}$  synthesis causing low serum  $1,25(\text{OH})_2\text{D}$  and impaired  $1,25(\text{OH})_2\text{D}$  endocrine and autocrine/paracrine actions. Vitamin D supplementation can improve the impaired substrate availability for renal and non-renal  $1,25(\text{OH})_2\text{D}$  production by  $1\alpha$ -hydroxylases, normalize serum  $1,25(\text{OH})_2\text{D}$  levels and may also improve autocrine  $25(\text{OH})\text{D}$  synthesis.  $1,25(\text{OH})_2\text{D}$  replacement therapy can correct the reduced renal megalin content and the defective  $25(\text{OH})\text{D}$  uptake by non-renal cells but cannot correct  $25(\text{OH})\text{D}$  deficiency. Thus, the combination of nutritional vitamin D and  $1,25(\text{OH})_2\text{D}$  (or analogs) replacement therapy may simultaneously enhance  $25(\text{OH})\text{D}$  availability and improve renal and non-renal  $25(\text{OH})\text{D}$  uptake for endocrine and/or autocrine–paracrine actions of the  $1,25(\text{OH})_2\text{D}$ /VDR complex.

The assessment of changes in vitamin D metabolite ratios rather than single metabolite measurements could help personalize the design of safer and more effective vitamin D interventions. The identification of impaired catabolism of vitamin D metabolites in CKD calls for extreme caution to avoid vitamin D toxicity, particularly when using  $25(\text{OH})\text{D}$  to correct vitamin D deficiency or when simultaneously targeting vitamin D and  $1,25(\text{OH})_2\text{D}$  deficiency.

## 6. Alterations in $1,25(\text{OH})_2\text{D}$ /VDR endocrine and autocrine/paracrine actions in CKD

Most of  $1,25(\text{OH})_2\text{D}$ 's biological actions require its binding to the VDR, a member of the thyroid/retinoid nuclear receptor superfamily. The so-called “classical” genomic actions of the  $1,25(\text{OH})_2\text{D}$ /VDR complex (summarized in Fig. 79.5) involve ligand binding to the VDR,

**FIGURE 79.5** Abnormal VDR regulation of gene transcription in CKD. 1,25(OH)<sub>2</sub>D (1,25D)/VDR-transcriptional control of the expression of vitamin D-responsive genes involves ligand binding to VDR; VDR heterodimerization with RXR; DNA binding of the VDR/RXR complex, and recruitment of basal transcription factors (B), coregulator molecules (CoReg), and RNA polymerase II to activate or repress gene transcription, including genes coding for microRNA molecules. Kidney disease induces several mechanisms (listed on the left) responsible for impairing critical steps (indicated by blue arrows) in 1,25(OH)<sub>2</sub>D/VDR transcriptional activity. CKD, chronic kidney disease; RXR, retinoid X receptor; VDR, vitamin D receptor; VDRE, vitamin D-responsive element.

which induces a conformational change in the VDR molecule that facilitates heterodimerization with its major transcriptional partner, the retinoid X receptor (RXR), followed by the binding of the VDR/RXR complex to vitamin D-responsive sequences (VDREs) on the promoter regions of vitamin D-responsive genes to induce/repress their expression (see Chapters 10–13). Unliganded VDR can bind DNA and transcriptionally repress gene expression in a ligand-independent manner [111]. Among the different VDRE sequences, those consisting of two direct imperfect repeats with a spacer of three nucleotides (DR3) are associated with the highest affinity for the VDR. The ligand-activated VDR/RXR complex binds simultaneously to multiple VDREs within 100 kb either 5' or 3' from the transcription start site of a target gene rather than to a single VDRE, as demonstrated by conformation capture technology [112]. Distal and more proximal VDREs are juxtaposed by chromatin looping, thus facilitating the simultaneous recruitment of basic transcription factors, coactivator, and/or corepressor molecules at multiple VDR–RXR/VDRE complexes. The induction of the RANKL gene, essential in 1,25(OH)<sub>2</sub>D-driven osteoclastogenesis and bone resorption, is an example of the simultaneous occupation of multiple VDREs by the

VDR/RXR complex involved in its transactivation [113]. Similar single- or super-complexes of VDR/RXR bound to DNA transcriptionally activate/repress the expression of the 500–1000 genes that mediate the survival benefits of a normal vitamin D status, as will be specifically addressed for genes that influence CKD progression.

Furthermore, the suppression of CYP27B1 in renal proximal tubular cells by 1,25(OH)<sub>2</sub>D is another example that proximal regions in a gene promoter may play a role in transcriptional repression; however, unbiased genome-wide analysis has located four potent regulatory modules for the response to 1,25(OH)<sub>2</sub>D residing within specific introns in the adjacent genes *Mettl1* and *Mettl21b* [15,25].

A relevant developing field is 1,25(OH)<sub>2</sub>D/VDR transcriptional regulation of gene promoters that drive the expression of microRNAs (miRNAs) (Fig. 79.5) [114] (see Chapter 14). miRNAs are short (18–25 nucleotides) noncoding RNAs that bind the 3'-untranslated region of target mRNA decreasing either mRNA stability or protein translation, thereby controlling the expression of 30% of the genes in the genome. Highly relevant in CKD is 1,25(OH)<sub>2</sub>D (analog)-mediated upregulation of microRNA-145 in the vasculature [115] and the

induction of miR106b-5p secretion by circulating monocytes when macrophage VDR signaling is ablated [116]. While the former confers cardiovascular protection from calcium deposition, restenosis, and atherosclerosis, the latter has provided a causal link between immune cell activation by vitamin D deficiency and increased renin production by juxtaglomerular cells, as will be discussed in the following.

The  $1,25(\text{OH})_2\text{D}$ /VDR complex regulates gene transcription via several other mechanisms aside from direct repression or transactivation. The complex may induce genomic actions that involve an indirect control of the expression of an apparent target gene through the direct transcriptional control of an essential inducer or repressor. An example of such a mechanism is  $1,25(\text{OH})_2\text{D}$ -mediated suppression of ADAM17 gene expression to control parathyroid hyperplasia through the induction of C/EBP $\beta$  [117]. Alternatively, the cytosolic  $1,25(\text{OH})_2\text{D}$ /VDR complex may also bind main transcriptional regulators in signaling pathways unrelated to vitamin D biological actions that can drastically modify their transcriptional activity. An important example in CKD is the physical interaction of the VDR with  $\beta$ -catenin in the vasculature, which results in impaired Wnt activation to diminish vascular calcification [118] and the rapid progression of diabetic nephropathy to end-stage renal disease [119]. The  $1,25(\text{OH})_2\text{D}$ /VDR complex also affects the rates of mRNA translation, essential to maintain viability in cells forced to mount acute responses to counteract life-threatening conditions as starvation or strong growth signals. An important example of this process is vitamin D-mediated suppression of mammalian target of rapamycin (mTOR), as first demonstrated in breast cancer [120]. In CKD, this mechanism attenuates parathyroid gland enlargement [121] and VDR reductions, as will be discussed in the section on vitamin control of SHPT.

$1,25(\text{OH})_2\text{D}$  also exerts less well characterized rapid “nongenomic” actions, which occur within minutes of exposure to  $1,25(\text{OH})_2\text{D}$  and also involve the cytosolic VDR, although other potential receptors such as MARRS have been identified [122,123]. These rapid actions have the capacity to regulate intracellular calcium fluxes, as well as the degree of protein phosphorylation, acetylation, and subcellular localization to modify protein function and genomic signals (reviewed in Ref. [122]). The impact of these rapid vitamin D actions on pathways regulating the stability and/or processing of miRNAs and the intracellular trafficking by soluble klotho to improve survival is not known.

The intracellular levels of  $1,25(\text{OH})_2\text{D}$  and VDR determine the magnitude of  $1,25(\text{OH})_2\text{D}$ /VDR complex formation and, consequently, the efficacy for direct or indirect gene transactivation/trans-repression by the  $1,25\text{D}$ /VDR complex. Since both circulating

$1,25(\text{OH})_2\text{D}$  levels and local synthesis as well as cellular VDR content are reduced in CKD, VDR-mediated regulation of gene expression is greatly altered [19]. The vitamin D deficiency and  $1,25(\text{OH})_2\text{D}$  deficiency in CKD patients could also directly contribute to VDR reductions because  $1,25(\text{OH})_2\text{D}$  binding protects the VDR from proteosomal degradation [124]. Thus, when treating SHPT, the correction of vitamin D deficiency recommended by KDIGO guidelines could attenuate VDR reductions and, consequently, delay the escalation in  $1,25(\text{OH})_2\text{D}$  dosage required to compensate for lower parathyroid VDR levels, thereby ameliorating the risk of hypercalcemia, hyperphosphatemia, and propensity to calcifications.

In the course of CKD, reductions in cellular RXR content and accumulation of uremic toxins result in decreased  $1,25(\text{OH})_2\text{D}$ /VDR–RXR complex formation and the binding of the VDR/RXR complex to DNA, respectively, further decreasing the already defective response to vitamin D therapy caused by low VDR (Reviewed in Ref. [125]). Hypocalcemia associated with CKD increases nuclear levels of calreticulin, a protein that interacts with the DNA-binding domain of nuclear receptors including the VDR, further compromising  $1,25(\text{OH})_2\text{D}$ /VDR genomic actions [126]. The low serum  $1,25(\text{OH})_2\text{D}$  found in CKD could also affect the expression of essential coactivators or corepressor molecules [127] or the proper translational modifications required for their recruitment to the VDR transcription preinitiation complex. In fact, selective recruitment of corepressor molecules by  $1,25(\text{OH})_2\text{D}$  analogs contributes to their diverse potency in suppressing PTH gene expression *ex vivo* [128]. However, all of these CKD-induced adverse molecular interactions are tissue- and gene-specific, not measurable *in vivo*, and consequently, do not provide appropriate therapeutic targets.

Fig. 79.2 presents a previously unrecognized synergy between  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  for VDR activation that could be exploited to safely counteract CKD-induced impairments in the formation and transcriptional function of the  $1,25(\text{OH})_2\text{D}$  (analog)/VDR complex, thus improving the health benefits of VDR activation in CKD without escalating  $1,25(\text{OH})_2\text{D}$  (analog) dosage. Studies in the CYP27B1-null mouse [129], which lacks the enzyme that converts  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$ , and *in vitro* studies using  $25(\text{OH})\text{D}$  analogs chemically modified to prevent hydroxylation at carbon 1 [130,131], have conclusively demonstrated that  $25(\text{OH})\text{D}$  activates the VDR directly and also synergizes with  $1,25(\text{OH})_2\text{D}$  activation of the VDR, as will be described by the efficacy of the  $25(\text{OH})\text{D}$ /paricalcitol combination to overcome parathyroid VDR resistance to suppress PTH and parathyroid cell growth in a rat model of hyper-phosphatemic kidney disease [117].

The concurrence of vitamin D and  $1,25(\text{OH})_2\text{D}$  deficiency with VDR reductions in CKD patients makes this synergy a valuable tool to improve clinical outcomes without escalating  $1,25(\text{OH})_2\text{D}$  (analogs) doses. Furthermore, since 25-hydroxylases are ubiquitously distributed and are not as tightly regulated as the constitutive renal CYP27B1 and CYP24A1 enzymes, local  $25(\text{OH})\text{D}$  production following cholecalciferol supplementation could safely counteract the reductions in intracellular levels of  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  or of the  $1,25(\text{OH})_2\text{D}$ /VDR complex induced by CKD with minimal impact on serum  $25(\text{OH})\text{D}$  levels or systemic calcium and phosphorus homeostasis.

The next section updates our understanding of the most critical vitamin D actions to attenuate CKD progression and improve skeletal and cardiovascular outcomes with the goal of identifying accurate and sensitive early biomarkers of the efficacy of vitamin D interventions to increase survival with minimal risk of toxicity.

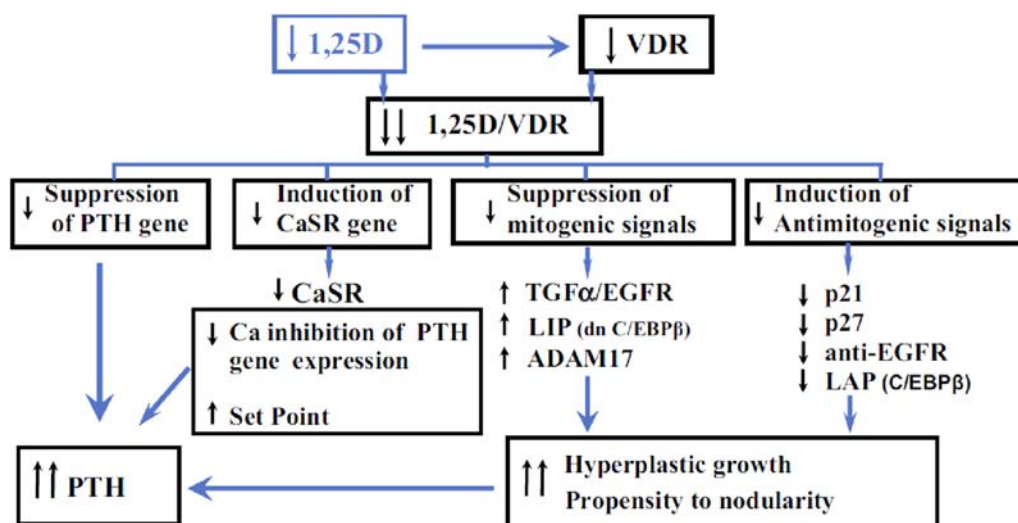

## 7. Vitamin D control of secondary hyperparathyroidism

Nearly all patients with end-stage renal disease develop SHPT, a condition characterized by parathyroid hyperplasia and increased synthesis and secretion of PTH, which severely affects skeletal and vascular health, markedly increasing morbidity and mortality rates. Three decades of experience with the clinical challenge of counteracting the onset of parathyroid resistance to either  $1,25(\text{OH})_2\text{D}$  (analogs) replacement therapy or vitamin D supplementation has resulted in

the parathyroid gland being one of the best characterized targets of the vitamin D endocrine–autocrine/paracrine system (summarized in Figs. 79.2 and 79.6) (see Chapter 17).

Hypocalcemia, hyperphosphatemia due to phosphate retention, vitamin D, and  $1,25(\text{OH})_2\text{D}$  deficiency are the main causes of SHPT [132]. The transcriptional repression of the PTH gene by the  $1,25(\text{OH})_2\text{D}$ /VDR complex involves its binding to a “classical” negative VDRE on the PTH gene promoter [133]. The elevations in serum PTH levels in vitamin D–deficient individuals with normal kidney function [50] as well as the reductions in serum PTH with vitamin D supplementation at early stages of kidney disease [103] or in renal transplant recipients [45] all support a role for parathyroid  $1\alpha$ -hydroxylase and autocrine/paracrine VDR activation in PTH suppression (see Fig. 79.2).

Vitamin D and/or  $1,25(\text{OH})_2\text{D}$  deficiency also impair the response of the parathyroid gland to calcium due to reductions in parathyroid content of the calcium-sensing receptor (CaSR), as demonstrated in vitamin D–deficient rats [134] and CKD patients [135]. The CaSR gene is directly induced by  $1,25(\text{OH})_2\text{D}$  through VDR/RXR binding to VDREs in this gene promoter [136]. Accordingly,  $1,25(\text{OH})_2\text{D}$  treatment increases the CaSR content reducing the set point for PTH suppression by calcium [137]. Significantly,  $1,25(\text{OH})_2\text{D}$  upregulation of the CaSR plays a critical role in attenuating hyperphosphatemia-induced PTH secretion. In 2019, the CaSR was identified as the “phosphate sensor” [138]. Increases in serum phosphate concentrations, within the pathophysiological range of CKD, suppress CaSR activity through noncompetitive antagonism that stabilizes the CaSR molecule in an inactive

**FIGURE 79.6** Role of  $1,25(\text{OH})_2\text{D}$  deficiency in the pathogenesis of secondary hyperparathyroidism in chronic kidney disease. *CaSR*, calcium-sensing receptor; *CKD*, chronic kidney disease; *EGFR*, epidermal growth factor receptor; *PTH*, parathyroid hormone; *TGF*, transforming growth factor; *VDR*, vitamin D receptor.

conformation, leading to chronically stimulated PTH release. It is therefore possible that variations in the high serum phosphate in advanced CKD would differentially displace the CaSR toward an inactive conformation. This may partially explain the high variability in the response to calcimimetic drugs, which are CaSR agonists, to suppress PTH in hyperphosphatemic states.

1,25(OH)<sub>2</sub>D induction of FGF23 synthesis in bone cells of the osteoblast/osteocyte lineage provides an additional indirect mechanism for vitamin D suppression of PTH secretion and parathyroid hyperplasia in CKD, provided there is sufficient parathyroid or circulating klotho [139], another gene that is induced by the 1,25(OH)<sub>2</sub>D/VDR complex [13] and reduced in the parathyroid glands of CKD patients. FGF23 induction of parathyroid CYP27B1 mRNA levels [98] may also contribute to autocrine/paracrine PTH suppression.

Prolonged persistence of hypocalcemia or vitamin D deficiency induces parathyroid cell proliferation to meet the higher requirements of serum PTH to normalize serum calcium. Hyperphosphatemia also

stimulates parathyroid hyperplasia [140]. In turn, the hyperplastic growth results in not only higher serum PTH levels but also marked reductions in the parathyroid VDR, CaSR, FGF receptors, and cell membrane klotho, all of which impair PTH suppression by active vitamin D, oral calcium, or the early increases in FGF23 [141].

The increased TGF $\alpha$  content noted in parathyroid adenomas and diffusely hyperplastic and nodular glands from CKD patients [142] led to identification of the essential role of TGF $\alpha$  activation of its receptor, the EGFR, in the severity of parathyroid hyperplasia and VDR reductions [143]. Briefly, as summarized in Fig. 79.7, the release of mature TGF $\alpha$  from its transmembrane precursor by ADAM17, an enzyme essential for parathyroid gland development [144], initiates a powerful autocrine loop for excessive TGF $\alpha$ /EGFR-growth signals because TGF $\alpha$  induces its own gene expression [145] and that of the ADAM17 gene [144], in part through increases in AP2 and LIP, respectively. In turn, the increases in the oncogene LIP (also

**FIGURE 79.7** Pathogenesis of parathyroid hyperplasia and 1,25(OH)<sub>2</sub>D resistance in CKD and its reversal by combined vitamin D and 1,25(OH)<sub>2</sub>D administration. Increases in parathyroid ADAM17, ADAM17-mediated release of TGF $\alpha$ , TGF $\alpha$  activation of the EGFR, and TGF $\alpha$ /EGFR induction of the synthesis of AP2, an inducer of TGF $\alpha$  gene expression, and of the potent mitogen LIP (the dominant negative isoform of C/EBP $\beta$ , dn C/EBP $\beta$ ) causes a feed forward loop for exacerbated growth and propensity to nodular hyperplasia as LIP directly enhances ADAM17 gene transcription. Because LIP also exerts a dominant negative inhibition of VDR gene transcription, the reductions of parathyroid VDR content causing resistance to calcitriol therapy are directly proportional to the severity of the hyperplastic growth. 1,25(OH)<sub>2</sub>D suppresses activated-EGFR signaling as effectively as EGFR-tyrosine kinase inhibitors (EGFR-TKI). 25(OH)D synergizes 1,25(OH)<sub>2</sub>D induction of C/EBP $\beta$  counteracting a powerful vicious cycle for exacerbated growth and VDR reductions. CKD, chronic kidney disease; EGFR, epidermal growth factor receptor; TGF, transforming growth factor; VDR, vitamin D receptor.

called dominant negative C/EBP $\beta$ ) are responsible for the suppression of VDR gene expression [143]. The concurrent overexpression of proliferating signals, such as TGF $\alpha$ , ADAM17, and LIP, may contribute to the transformation of parathyroid growth from diffuse to nodular [146]. The essential role of EGFR activation in CKD-driven parathyroid hyperplasia, TGF $\alpha$  self-induction, and VDR reductions has been conclusively demonstrated by the parathyroid phenotype of nephrectomized mice harboring a parathyroid-specific EGFR inactivation [144].

1,25(OH) $_2$ D/VDR suppression of parathyroid cell growth involves transactivation of the growth suppressors p21 and p27 [147], and of C/EBP $\beta$ , a growth inhibitor and a trans-activator of the VDR gene [148]. The complex also promotes “non-classical” control of TGF $\alpha$ /EGFR-driven hyperplasia by regulating subcellular trafficking with sequestration of activated EGFR in early endosomes [149]. As a dominant negative C/EBP $\beta$ , LIP antagonizes C/EBP $\beta$  function so that the cellular C/EBP $\beta$ /LIP ratio determines the prevalence of growth arrest or excessive growth. Although the 1,25(OH) $_2$ D/VDR complex directly induces the expression of the C/EBP $\beta$  gene [148], the main regulation of cellular C/EBP $\beta$ /LIP ratios is at the level of translation of either molecule from a single C/EBP $\beta$  mRNA. TGF $\alpha$ /EGFR growth signals induce the translation of LIP over that of C/EBP $\beta$ , which results in LIP-driven induction of ADAM17 gene expression [117] and reduction of the VDR gene [143]. The efficacy of rapamycin, an mTOR inhibitor, in suppressing parathyroid hyperplasia [121] supports a role for the 1,25(OH) $_2$ D/VDR control of mTOR [120] in counteracting the abnormalities in the translational control of parathyroid C/EBP $\beta$ /LIP ratio in advanced CKD. The activation of mTOR induced by the onset of renal failure or hypercalcemia is central for the development of SHPT and parathyroid cell proliferation in a rat model of adenine-induced renal failure [121].

1,25(OH) $_2$ D/VDR suppression of ADAM17 gene expression, a key target “upstream” of EGFR activation, contributes to the synergy between 1,25(OH) $_2$ D and the EGFR-specific tyrosine kinase inhibitor erlotinib in controlling parathyroid hyperplasia in 5/6 nephrectomized rats fed high dietary phosphorus [117]. Importantly, in this rat CKD model, the erlotinib/1,25(OH) $_2$ D synergy, which cannot be used therapeutically in renal patients as erlotinib is prescribed for EGFR-driven carcinomas, can be safely mimicked by the intraperitoneal administration of a combination of 25(OH)D and the 1,25(OH) $_2$ D analog paricalcitol (Fig. 79.7). Briefly, a dose of 25(OH)D that corrects vitamin D deficiency but fails to control SHPT combined with a dose of paricalcitol also insufficient to suppress either serum PTH or parathyroid cell growth reduced serum PTH by 50%

and suppressed parathyroid ADAM17 as effectively as phosphorus restriction [117] despite similar serum calcium and phosphorus levels. Mechanistically, improved parathyroid 1,25(OH) $_2$ D synthesis and the synergy between 25(OH)D and 1,25(OH) $_2$ D for VDR activation can partly explain the higher efficacy of this combination to suppress PTH and inhibit parathyroid ADAM17. These findings may partially explain why the exclusive correction of vitamin D deficiency could be insufficient to reduce serum PTH even at early CKD stages [50]. Also, vitamin D supplementation may benefit advanced CKD patients unresponsive to therapy, whose mild elevations in serum calcium and phosphorus impede escalating 1,25(OH) $_2$ D (analogs) dosage.

The oral formulations for cholecalciferol and active vitamin D therapy currently available may compromise the safety of the intraperitoneal route used in rat CKD studies. Specifically, the same 25(OH)D/active vitamin D synergy for intestinal VDR activation will increase calcium and phosphorus absorption aggravating hypercalcemia or hyperphosphatemia. Intestinal 25(OH)D/paricalcitol (1,25(OH) $_2$ D) synergy and CKD-induced impairments in 1,25(OH) $_2$ D (analogs) catabolism despite increased 24-hydroxylase mRNA levels [88,89] will markedly increase the risk of hypercalcemia and hyperphosphatemia. A safer option would be to escalate the dosage of vitamin D supplements to increase parathyroid 25(OH)D synthesis while reducing or maintaining existing 1,25(OH) $_2$ D (analogs) doses to avoid vitamin D toxicity.

For decades, the safe control of serum PTH by 1,25(OH) $_2$ D (analogs) to avoid hypercalcemia, hyperphosphatemia, and PTH over-suppression has been the treatment of choice for renal osteodystrophy. The goal is to prevent hyperphosphatemia and high PTH-induced increases in arterial calcium deposition promoting hypertension, cardiac overload, LVH, and high risk of cardiovascular mortality [7]. The COSMOS study, a large prospective study with a 3 year follow-up of the clinical handling of CKD-5D patients throughout Europe, has provided a range within the U-shaped curve for serum PTH that correlates with the lowest relative risk of mortality [150]. The clinical relevance of this PTH range was further corroborated by the survival benefits of correcting serum PTH to values within this range. Therefore, 1,25(OH) $_2$ D/analog suppression of PTH was also considered a mediator of the improvements in cardiovascular outcomes. However, 1,25(OH) $_2$ D (analog) induction of serum FGF23, a direct stimulus of pathological LVH through its activation of FGFR4-calcineurin pathway in cardiomyocytes [14], has suggested that prevention of the elevations of FGF23 would be more effective than PTH suppression to control LVH and cardiovascular risks in advanced CKD. Indeed, a very recent study by Dorr and

collaborators has compared the efficacy of etelcalcetide, a calcimimetic drug indicated for SHPT, with that of the VDR agonist alpha-calcidol, which is activated to 1,25(OH)<sub>2</sub>D in the liver, at controlling changes in LVH after a 12 month treatment [151]. In the primary intention to treat analysis, the changes in left ventricular mass index favored etelcalcetide over alpha-calcidol. Furthermore, the magnitude of the changes in LVMI was independently associated with FGF23 reductions [151], suggesting that reductions in FGF23 rather than PTH suppression could better estimate the cardiovascular risk in ESRD patients [152]. However, it is important to consider the multiple determinants of high FGF23 in CKD unrelated to 1,25(OH)<sub>2</sub>D (analog) therapy and, more significantly, that 1,25(OH)<sub>2</sub>D (analog) could further improve calcimimetic amelioration of serum FGF23 by (1) Reducing FGFR4 expression in cardiomyocytes to impair FGF23/FGFR4 induction of LVH [153]; (2) Maintaining circulating s-klotho to force FGF23 to switch from a klotho-independent binding to FGFR4-driven signaling to a s-klotho-dependent formation of a protective s-klotho/FGFR1/FGF23 complex [17], (3) Inducing the expression of the CaSR to ameliorate hyperphosphatemia-induced displacement of the CaSR toward an inactive conformation, thus improving calcimimetic suppression of PTH [136,138].

The next section highlights 1,25(OH)<sub>2</sub>D/VDR actions for skeletal protection in CKD unrelated to an effective control of SHPT.

## 8. Vitamin D control of skeletal health in CKD unrelated to the attenuation of secondary hyperparathyroidism

In CKD, the combination of vitamin D and/or 1,25(OH)<sub>2</sub>D insufficiency/deficiency, the onset of resistance to vitamin D therapy due to low VDR in bone cells, high PTH, and reduced renal klotho contribute to a wide range of bone disorders that predispose to vascular calcifications and increased risk for cardiovascular mortality. Several landmark studies have demonstrated the essential role of vitamin D for normal skeletal development and mineralization since the initial discovery that vitamin D deficiency was the cause of rickets, more than a century ago. However, the subtle abnormalities in bone mineral density in the VDR-null mouse fed an adequate supply of calcium and phosphorus (the so-called rescue diet) suggested that the VDR was dispensable for the ossification process [154]. Comprehensive studies in the VDR-null, 1 $\alpha$ -hydroxylase-null, and PTH-null mice, as well as multiple double knockout combinations, have revealed the essential role of 1,25(OH)<sub>2</sub>D for the induction of osteoblastogenesis,

skeletal anabolism, and the appropriate coupling of osteoblastic and osteoclastic activity [155,156].

The 1,25(OH)<sub>2</sub>D/VDR complex regulates the expression of genes that control bone formation, mineralization and remodeling (osteopontin, osteocalcin, and the Wnt receptor LRP5), and osteoclastogenesis and bone resorption (RANK ligand (RANKL) and osteoprotegerin (OPG)) through classical genomic actions (reviewed in Ref. [133]). In health, the physiological or supra-physiological concentrations of serum 1,25(OH)<sub>2</sub>D determine the prevalence of bone formation over resorption. In addition, the stage of differentiation of cells of the osteoblastic lineage determines 1,25(OH)<sub>2</sub>D actions. 1,25(OH)<sub>2</sub>D anabolic and anti-catabolic properties prevail in more mature cells, as conclusively demonstrated by overexpression of the VDR in mature osteoblasts in vivo [157]. Therefore, the coexistence of all of these distinct cell maturation stages in bone may partially explain the existing controversies regarding the prevalence of 1,25(OH)<sub>2</sub>D anabolic or catabolic actions in bone.

In mouse and rat CKD models, 1,25(OH)<sub>2</sub>D and its analog paricalcitol similarly maintained bone anabolism but differed in their osteoclastogenic potency [158,159] through a distinct regulation of several critical genes for bone remodeling. High 1,25(OH)<sub>2</sub>D potently induces RANKL and suppresses the expression of its decoy receptor OPG amplifying resorptive signals. Defective induction of osteopontin by the 1,25(OH)<sub>2</sub>D/VDR complex in CKD could adversely impact remodeling and osteoclast recruitment to resorb ectopic bone (reviewed in Ref. [133]). Similarly, an impaired induction of osteocalcin could negatively affect bone strength and energy metabolism through osteocalcin-mediated insulin release [160].

The accumulation of the Wnt inhibitors sclerostin and Dkk1 during CKD progression [161] generated great interest in CKD-induced defects in Wnt signaling in osteocytes and osteoblasts. This process is critical for skeletal development and mineralization, and consequently, is a potential contributor to the strong association between bone loss and increased vascular calcification [162]. Impaired 1,25(OH)<sub>2</sub>D induction of the LRP5 gene, involved in Wnt pathway activation, could contribute to bone loss in CKD. Although LRP5 induction by the VDR appears to occur regardless of 1,25(OH)<sub>2</sub>D VDR binding [124], CKD also reduces VDR content and its biological half-life.

A comprehensive examination of the mechanisms for the onset of abnormalities in Wnt pathway activation from early CKD stages has questioned the higher value for measurements of serum sclerostin levels over serum PTH in estimating skeletal damage [161] and has also revealed additional mechanisms for skeletal protection by a normal vitamin D status. Specifically, studies in a

mouse model of polycystic kidney disease, which reproduces a slow progression of human CKD, have demonstrated that the impaired Wnt activation in bone occurs before elevations in serum PTH [163]. Furthermore, in both mouse and rat CKD models, bone sclerostin decreases below the level of sham-operated controls as serum PTH and FGF23 increase. Clearly, this early increase in bone sclerostin is independent of the severity of SHPT. Instead, the progressive loss of bone mass in these experimental models was paralleled by elevations in bone levels of several Wnt inhibitors other than sclerostin, including Dkk1 [163–165]. Accordingly, bone biopsies in CKD patients corroborated a strong Wnt inhibition despite a lower number of osteocytes positive for sclerostin [163], thus questioning the accuracy of serum sclerostin to reflect not only the degree of Wnt inhibition in bone but also bone sclerostin levels. These studies have also demonstrated an unprecedented direct role for high FGF23 on Wnt inhibition in osteoblasts through the induction of Dkk1 [164].

The prevention of the early increases in bone sclerostin and loss of bone mass in this mouse CKD model with a TGF $\beta$  antibody [165] suggested that CKD induces early increases in TGF $\beta$  to promote Wnt inactivation. Therefore, a normal vitamin D status could help attenuate CKD-induced onset of adverse TGF $\beta$ /Smad signaling in bone, as VDR signaling antagonizes TGF $\beta$ /Smad-dependent transcriptional activation of several profibrotic genes through the recruitment of VDR to loci on these genes that prevent/attenuate Smad3 binding [166]. An important additional benefit of vitamin D–dependent regulation of the Wnt pathway is that it is tissue-specific. For instance, in the kidney and the vasculature where Wnt activation worsens the progression of renal damage and vascular calcification, vitamin D inhibits Wnt signals [167,168] through VDR binding to  $\beta$ -catenin in the cytosol preventing its translocation to the nucleus [118,169].

Another controversial issue is whether 1,25(OH) $_2$ D induction of FGF23 synthesis in bone could act as an autocrine–paracrine mineralization-regulating factor in osteocytes and osteoblasts since both FGF23 excess and deficiency lead to inhibition of bone formation and mineralization [170]. These opposing FGF23 effects are partly explained by either suppression (in the case of FGF23 excess) or induction (in the case of FGF23 deficiency) of tissue non-specific alkaline phosphatase (TNAP) in a klotho-independent manner (reviewed in Ref. [171]). While suppression of TNAP leads to accumulation of pyrophosphate, a mineralization inhibitor, the high release of inorganic phosphate by increased TNAP results in the induction of osteopontin, another mineralization inhibitor [171]. As mentioned, FGF23 also impairs bone formation through the induction of the Wnt inhibitor Dkk1 [164].

The role of reductions of bone cell klotho in CKD in the maintenance of skeletal integrity is also a highly controversial issue. Indeed, contrary to the reductions in bone density and cortical bone thickness in the klotho hypomorphic mouse, specific ablation of the klotho gene in osteocytes resulted in increased osteoblastic activity and bone formation rates [172]. Since klotho is the most powerful inducer of FGF23 in bone, it is possible that klotho deletion prevents/attenuates the deleterious impact of high FGF23 on bone mineralization. Intriguingly, despite the markedly reduced osteocyte klotho levels in an experimental mouse CKD model, there were no improvements in bone density [172], suggesting that CKD also impairs the normal function of the FGF23/klotho axis to protect the bone.

The next section addresses CKD-induced alterations of the FGF23-klotho/1,25(OH) $_2$ D/phosphate axis.

## 9. Vitamin D maintenance of renal FGF23/klotho axis: relevance for renal and cardiovascular protection

1,25(OH) $_2$ D/VDR-mediated regulation of FGF23 and klotho expression to maintain a normal bone–kidney–parathyroid FGF23/klotho axis is crucial for survival. In individuals with normal renal function, 1,25(OH) $_2$ D/VDR transactivation of the FGF23 gene in osteocytes and osteoblasts facilitates the pro-survival actions of vitamin D via two mechanisms. First, FGF23 promotes the renal elimination of phosphorus to prevent hyperphosphatemia and its pro-aging consequences. Second, it suppresses renal 1,25(OH) $_2$ D synthesis and induces 25(OH)D and 1,25(OH) $_2$ D catabolism in the kidney and non-renal cells to avoid vitamin D toxicity. In fact, the main features of the FGF23-null mouse are hyperphosphatemia, high circulating 1,25(OH) $_2$ D, ectopic calcifications, premature aging, arteriosclerosis, and osteoporosis [173], a severe phenotype that can be rescued by dietary phosphorus restriction [68,174,175]. It should be noted that hyperphosphatemia enhances serum FGF23 by increasing the half-life of the FGF23 protein through binding to FGFR1, resulting in upregulation of the *galnt3* gene, which is responsible for the O-glycosylation of full-length FGF23 that impedes its intracellular inactivating cleavage [24].

The low serum FGF23 in VDR- and CYP27B1-null mice [176] suggests that an impaired induction of FGF23 during vitamin D deficiency contributed to their accelerated pro-aging features and mortality rates. However, because double knockouts of FGF23 and either the VDR [177] or CYP27B1 [178] could rescue the severe pro-aging features of the FGF23-null mice by preventing hyperphosphatemia, 1,25(OH) $_2$ D induction of FGF23 is

nowadays considered an adverse effect of 1,25(OH)<sub>2</sub>D replacement therapy in CKD.

In the past 6 years, it has become clear that 1,25(OH)<sub>2</sub>D replacement is not the main reason for the abnormally high FGF23 levels in advanced CKD. Several factors, unrelated to alterations in bone and mineral metabolism, contribute to increased serum FGF23 in CKD (reviewed in Ref. [16]). These include reductions in dentin matrix protein I (DMP1) expression, the enzyme responsible for the cleavage of FGF23 for its inactivation [179]; hypoxia, a direct inducer of FGF23 gene transcription and stability [180]; increased release of glyceraldehyde 3 phosphate by the acutely damaged kidney, which induces bone FGF23 production [181]; and systemic inflammation [182], with LPS, IL-1 $\beta$ , and TNF being the main inducers of FGF23 gene transcription [183].

Significantly, inflammatory signals affect FGF23 production not only in bone but also in the thymus and spleen [184], and, in the case of LPS, FGF23 induction also occurs despite hypo-phosphatemic conditions. Instead, high 1,25(OH)<sub>2</sub>D fails to trans-activate the FGF23 gene under hypo-phosphatemic conditions, as demonstrated in a transgenic mouse with an ablation in the gene for the phosphorus transporter NPT2a [185]. Furthermore, neither hyperphosphatemia nor PTH, the latter inducing FGF23 gene transcription through the same enhancer utilized by inflammatory cytokines [168], is able to increase serum FGF23 if serum calcium is below 4 mg/dL [23].

The plethora of FGF23 inducers in CKD suggests that 1,25(OH)<sub>2</sub>D therapy is not the sole contributor to increased LVH risk associated directly with the high serum FGF23 in these patients. To the contrary, it suggests that 1,25(OH)<sub>2</sub>D anti-inflammatory actions could attenuate the elevations of circulating FGF23 induced by inflammatory cytokines. Also, 1,25(OH)<sub>2</sub>D-mediated reduction in FGFR4 [153] should attenuate the kloθο-independent FGF23-driven PLC $\gamma$ /calcineurin/NFAT pathway involved in promoting LVH [14,17].

1,25(OH)<sub>2</sub>D/VDR induction of the longevity gene  $\alpha$ -kloθο is essential for FGF23 phosphaturic [186] and PTH-suppressing actions [187], which require kloθο to form a stable ternary complex with FGF23 and FGFR1c to promote FGF23 signaling. Indeed, the early and progressive reductions in renal kloθο in the course of CKD progression contribute to the onset of renal resistance to FGF23 phosphaturic actions. Studies in CKD patients' stage 3–4 have demonstrated that progressive reductions of renal kloθο associate not only with a reduced fractional excretion of phosphate in response to FGF23 but also with a four-fold higher propensity for abdominal aortic calcification [188].

In opposition to our initial understanding that FGF23 resistance in CKD was limited to the few tissues

harboring kloθο, including the kidney, the parathyroid gland, and the choroid plexus [189], crystal structure analysis has now revealed soluble kloθο as a component of the FGF23/FGFR1c complex [17]. This recent finding provides a mechanism by which hyperphosphatemia is avoided and normal 1,25(OH)<sub>2</sub>D levels are maintained despite high FGF23 levels in a mouse model harboring a conditional kloθο deletion in renal proximal tubular cells, where phosphate reabsorption and 1,25(OH)<sub>2</sub>D synthesis take place [69].

Soluble kloθο (sKloθο) is released to the circulation upon cleavage of the transmembrane 140 kDa full-length kloθο molecule by the proteases ADAM17 and ADAM10 [190]. sKloθο may attenuate the pathological impact of high FGF23 in the heart of CKD patients through its binding to FGFR4 to simultaneously increase FGF23 binding affinity and block the kloθο-independent PLC $\gamma$ /calcineurin/NFAT pathway responsible for cell contractility, altered intracellular calcium, and hypertrophic cell growth. Instead, kloθο-dependent RAS/MAPK signaling is protective against adverse cardiac events [17]. sKloθο attenuation of FGF23 pathological actions could also extend to the amelioration of renal phosphate excretion through the binding of residual FGFR1 molecules in proximal tubular cells to increase FGF23 binding affinity and phosphaturic signaling [17].

Undoubtedly, the progressive reductions in renal content of the longevity gene kloθο also increase mortality rates in the course of CKD due to accelerated skeletal, immune, renal, and cardiovascular aging through FGF23-independent mechanisms [191]. Because a kidney-specific kloθο ablation mimicked the accelerated skeletal, immune, renal, and cardiovascular aging phenotype of the kloθο-null mice [192] and a VDRE was identified in the human kloθο promoter [13], a defect in vitamin D induction of renal kloθο was assumed to mediate, at least in part, the epidemiological association between vitamin D deficiency and higher risk of all-cause mortality in the general population [52], a risk that is markedly exacerbated in CKD patients [10]. Indeed, increased mortality rates were identified in hemodialysis patients carrying a kloθο polymorphism that impaired function. Moreover, survival rates were improved by 1,25(OH)<sub>2</sub>D (analog) administration [193], but it is unclear if the increased survival was the result of elevations in the defective renal kloθο or of direct pro-survival actions of active vitamin D therapy unrelated to renal kloθο induction.

sKloθο exerts a wide range of cellular functions beyond the tight regulation of mineral metabolism, which contribute to renal and cardiovascular protection [194] and increased survival [26,29]. These actions include inhibition of Wnt signaling, apoptosis, inflammatory signaling, fibrosis, as well as induction of

autophagy, preservation of stem cells, and maintenance of endothelial cell function to avoid the development of hypertension. In mice with normal kidney function, klotho-induced autophagy by disruption of the formation of the Beclin1/Bcl2 complex [195] is one of the mechanisms critical for klotho prevention of premature aging and life span improvements, which are unrelated to the attenuation of hyperphosphatemia. Similar klotho-mediated increases in autophagic flow partly explain why systemic administration of recombinant klotho or intravenous injection of urinary vesicles rich in klotho [196] rescues the renal and cardiovascular damage associated to acute or chronic renal injury in mice [197–199]. Importantly, despite a complete recovery of renal function after AKI, there is a later progression to CKD. In mice, klotho/s-klotho induction of autophagic flow attenuates the progression of acute kidney injury (AKI) to CKD after either bilateral ischemia reperfusion injury or unilateral ischemia with unilateral nephrectomy [200]. Indeed, while klotho haploinsufficient mice progressed to CKD much faster, klotho overexpressing mice were protected, an effect also mimicked by administration of recombinant  $\alpha$ -klotho that was associated with increases in renal cell autophagic flow. However, the contribution of the antioxidant, anti-apoptotic actions of sKlotho cannot be ruled out.

In diabetic kidney disease, decreases in serum klotho associate with the severity of albuminuria and renal insufficiency [201]. Conversely, klotho overexpression in spontaneously diabetic mice halts kidney disease progression [202,203]. Klotho-mediated inhibition of the Wnt/ $\beta$ -catenin pathway is the main mechanism by which kidney disease progression is avoided in diabetes [204]. Significantly, the administration of a small peptide of 30 amino acids, comprising the Gln186 to His 215 of the klotho molecule to a mouse model of streptozotocin-induced diabetes type 1 or to genetic db/db type 2 diabetic mice, was sufficient to attenuate glomerular hypertrophy, podocyte injury, glomerulosclerosis, and interstitial fibrosis without significant changes in serum calcium or phosphate levels [205]. The actions of this mini-klotho molecule involve inhibition of  $\beta$ -catenin activation without affecting Wnt expression. Specifically, the small klotho peptide binds Wnt ligands decreasing their ability to interact with lipoprotein receptor-related protein 5/6 (LRP5/6), thereby impeding LRP6 phosphorylation and  $\beta$ -catenin activation.

Since excessive Wnt signaling contributes to osteogenic differentiation of vascular smooth muscle cells promoting arterial calcification [206], the benefits of klotho-derived peptides may also extend to vascular protection. Thus, in diabetes, klotho-derived peptides provide a potentially effective approach to alleviate the

failure of current therapies aimed at improving glycemic control or inhibiting the renin–angiotensin–aldosterone system or sodium glucose co-transporter 2 to slow renal progression to end-stage renal disease.

Soluble klotho also acts at the apical site of the renal tubule as a glucuronidase enzyme to induce phosphaturia, urinary K excretion, and calcium reabsorption (reviewed in Ref. [207]). Different from the FGF23/FGFR1/klotho complex that decreases phosphate cotransporters at the cell surface [175], sKlotho cleaves residues that promote the endocytosis of the sodium–phosphate cotransporter NPT2a, thereby impeding phosphorus entrance into tubular cells provided there is sufficient megalin [208].

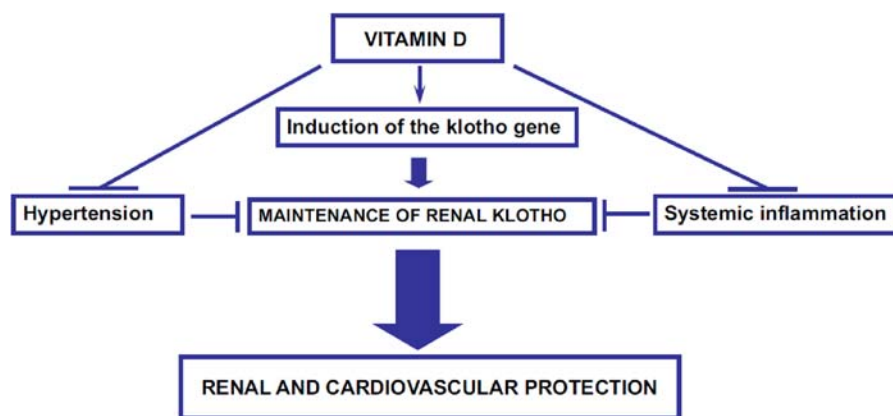

Circulating klotho also induces posttranslational modifications on the calcium channel TRPV5 to fix the protein to the cell surface enhancing renal calcium uptake [209] and leading to a positive bone calcium balance [210]. The recently solved crystal structure of the FGF23/FGFR/klotho complex has excluded the klotho sialidase activity, thought to mediate sKlotho modulation of TRPV5 and the K channel ROMK1, and suggested that sKlotho may act as a lectin that binds specific sugar residues in these channels to target them to the apical membrane [29]. Defective maintenance of renal TRPV5 activity due to impaired klotho transcytosis to the urinary side by a failing kidney could contribute to the direct correlation between serum klotho higher than normal, negative calcium balance, and increased incidence of fractures.

Overall, preventing the reduction of renal and/or circulating klotho is essential to reduce the severity of CKD progression and the risk for cardiovascular mortality. Indeed, serum s-klotho decreases with age, incidence of hypertension [211], and systemic inflammation [212] all recognized determinants of renal damage and cardiovascular disease. Vitamin D also maintains renal klotho content through the control of hypertension and systemic inflammation (Fig. 79.8).

The main contribution of the kidney to serum s-klotho levels was strongly supported by an 80% reduction in circulating s-klotho upon specific ablation of renal klotho [192]. This finding was critical to consider that serum s-klotho levels could be an accurate biomarker of renal klotho content, CKD progression, and cardiovascular mortality risk in CKD patients. However, the kidney is also the main organ for the clearance of circulating klotho into the urine, through a process of transcytosis through tubular cells [213]. Therefore, increases in circulating s-klotho could reflect an impaired transcytosis to the urine by the damaged kidney, which may mask both actual renal klotho reductions and potential improvements in renal klotho content induced by vitamin D interventions. Also, current assays fail to discriminate full-length klotho from

**FIGURE 79.8** Vitamin D maintenance of renal klotho contributes to renal and cardiovascular protection. Vitamin D simultaneous induction of the klotho gene and inhibition of hypertension and systemic inflammation maintains renal klotho content, thereby ensuring klotho renal and cardiovascular protection.

shorter circulating isoform of unknown biological activity. Therefore, serum and urinary s-klotho are not accurate biomarkers of renal and cardiovascular risk at present. Improvements in the available assays and in sample preservation are mandatory first steps before establishing adequate ranges for serum and urinary s-klotho that are associated with the lowest mortality risk at different CKD stages [26].

As vitamin D restriction ameliorates the severe phenotype of the klotho-null mouse [67] and klotho suppresses CYP27B1 expression [68], avoiding excessive vitamin D interventions is essential for the proper functioning of this strong counter-regulatory loop between vitamin D and klotho to ensure survival, a challenge aggravated in CKD by an impaired vitamin D catabolism despite increased cyp24A1 expression [88,89].

### 10. Vitamin D control of hypertension and systemic inflammation conferring renal and cardiovascular protection independently of renal or systemic klotho levels

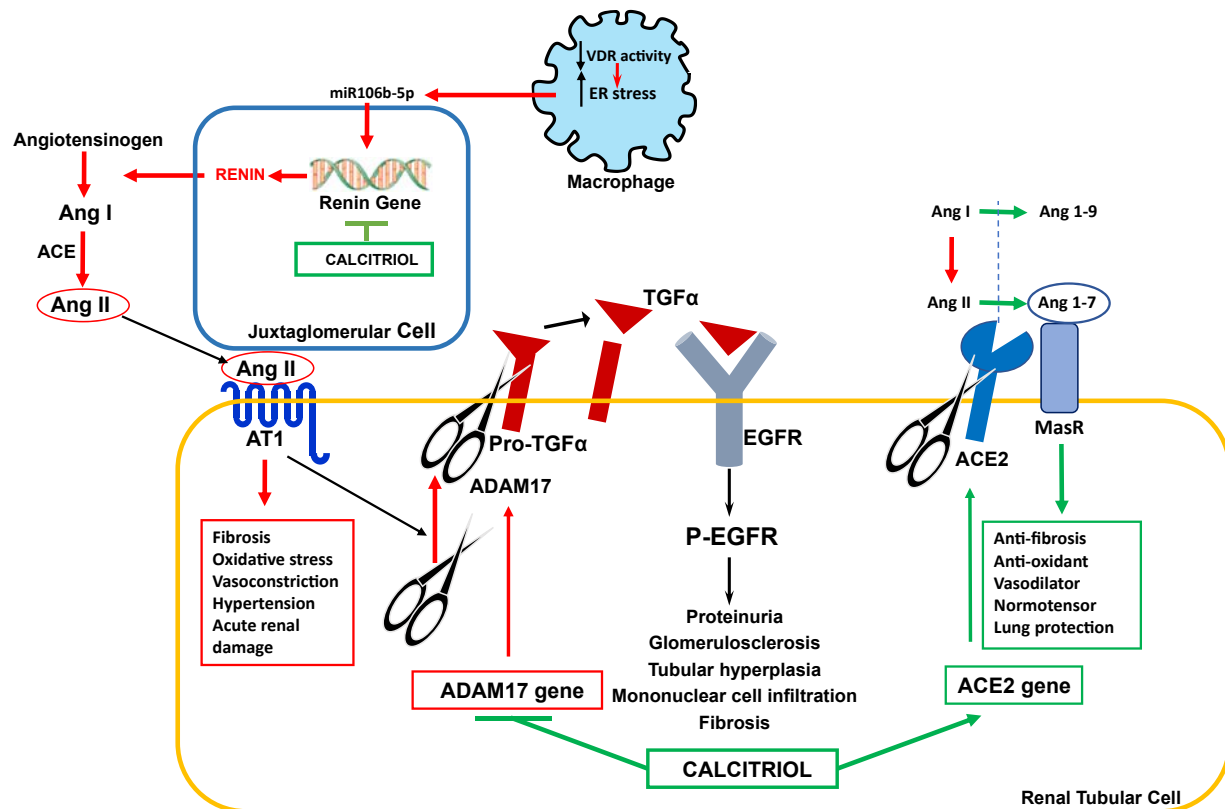

Vitamin D deficiency has been associated with the development of hypertension. 1,25(OH)<sub>2</sub>D/VDR inhibition of the renin gene [214] mediates in part the causal association between increases in circulating 25(OH)D levels and reductions in blood pressure and hypertension demonstrated by Mendelian randomization studies [215]. However, the results from randomized controlled trials in individuals with normal renal function are controversial, partly due to the inclusion of subjects with normal vitamin D levels or receiving anti-hypertensive medications as well as variable vitamin D interventions [216].

Vitamin D downregulation of renin production persists in renal disease. Simultaneous administration of the angiotensin receptor 1 (AT1R) inhibitor losartan and the 1,25(OH)<sub>2</sub>D analog paricalcitol in rodent models

of diabetic nephropathy effectively attenuated losartan-induced increases in renin, resulting in lower serum angiotensin II [217]. Downregulation of RAAS by 1,25(OH)<sub>2</sub>D (analog) therapy has also shown effective in reducing proteinuria, systemic inflammation, and cardio-renal syndrome progression [7]. However, the 1,25(OH)<sub>2</sub>D (analog)/VDR complex ameliorates angiotensin II-driven renal damage independently of its downregulation of renin-driven RAAS activation through the suppression of ADAM17 expression and the induction of the angiotensin-converting enzyme II (ACE2) gene expression, as summarized in Fig. 79.9.

Lautrette and collaborators have conclusively demonstrated that the renal damage after a prolonged exposure to high angiotensin II is caused by angiotensin II-induced translocation of ADAM17 from the cytosol to the cell membrane of renal proximal tubular cells to release TGF $\alpha$ . This process results in EGFR activation, causing tubular hyperplasia, fibrosing glomerulosclerosis, proteinuria, inflammatory infiltration to the renal parenchyma, and stabilization of cytosolic ADAM17 [218]. In fact, TAPI II, an ADAM17 inhibitor, as well as specific ablation of the EGFR in proximal tubular cells, markedly attenuated the development of severe renal lesions despite persistent hypertension. This mechanism is of high clinical relevance because, in a normal kidney, ADAM17 is expressed at low levels exclusively in the distal convoluted tubules; however, human CKD of any etiology markedly increases renal ADAM17/TGF $\alpha$  expression and signaling throughout the kidney [219].

Once the increased renal ADAM17 initiates the release of TNF $\alpha$  into the circulation, TNF $\alpha$  induces ADAM17 gene transcription [220], resulting in a positive feedback loop to further exacerbate renal ADAM17 expression, the release of TGF $\alpha$  driving renal damage, and TNF $\alpha$ -driven systemic inflammation and inflammatory renal damage. These processes are not responsive to anti-RAAS therapy but still suppressible by 1,25(OH)<sub>2</sub>D (analogs)-mediated inhibition of ADAM17 [117] and

**FIGURE 79.9** Antihypertensive properties of the 1,25(OH)<sub>2</sub>D–VDR complex. In juxtaglomerular cells, 1,25(OH)<sub>2</sub>D (calcitriol) suppression of renin gene expression ameliorates systemic hypertension by reducing circulating angiotensin II levels. In macrophages, decreased VDR activation leads to ER stress–dependent secretion of miRNA 106b-5p, which induces juxtaglomerular cell renin production. In renal tubular cells, calcitriol opposes angiotensin II–driven renal damage by inhibiting ADAM17-mediated increases in TGF/EGFR signals and inducing ACE2 expression to promote angiotensin 1–7/MAS receptor-mediated anti-hypertensive, anti-fibrotic, and anti-inflammatory signals.

TNFα gene expression (Fig. 79.9). Thus, combined suppression of renin and ADAM17 gene expression by 1,25(OH)<sub>2</sub>D may contribute to the synergy between paricalcitol and the angiotensin II–converting enzyme (ACE) inhibitor enalapril in reducing the inflammatory macrophage infiltration to the renal parenchyma in rat CKD [221].

In the vasculature, 1,25(OH)<sub>2</sub>D-mediated suppression of the ADAM17/TNFα loop should decrease TNFα-induction of vascular neutral sphingomyelinase-2 expression and activity, responsible for the release of pro-calcifying exosomes to propagate calcium deposition in the medial arterial layer [222].

1,25(OH)<sub>2</sub>D induction of ACE2 gene expression effectively counteracts angiotensin II–driven hypertensive, inflammatory, and pro-fibrotic signals, as depicted in Fig. 79.9. ACE2 catalyzes the conversion of both angiotensin I and angiotensin II into angiotensin 1–9 and angiotensin 1–7, respectively, thereby reducing circulating angiotensin II levels and ameliorating its deleterious renal and cardiovascular effects that follow RAAS hyper-activation [223]. In addition, angiotensin 1–7 binding to its receptor MAS activates anti-fibrotic,

anti-oxidant, and vasodilatory signals favoring multi-organ protection and normotension [224,225].

Since ADAM17 cleaves ACE2, the increased ADAM17 expression and activity of kidney disease patients may partly account for the strong correlation between increases in circulating ACE2 and classical cardiovascular risk factors, such as older age, diabetes, and male gender, all associated with a higher risk for cardiovascular events, in CKD patients with no history of cardiovascular damage [226]. Thus, the cardiovascular protection by 1,25(OH)<sub>2</sub>D and its analogs may result from the combination of ADAM17 suppression and ACE2 induction. In fact, in non-obese diabetic mice, the 1,25(OH)<sub>2</sub>D analog paricalcitol, alone or in combination with aliskiren, a direct renin inhibitor, effectively counteracted the rise in circulating soluble ACE2 levels associated with diabetes. Reduced ADAM17 expression, oxidative stress, and proteinuria [227] were also observed, emphasizing the renoprotective effects of ACE2 induction.

1,25(OH)<sub>2</sub>D also induces the expression of microRNA-145 (miR-145) [228], the prevalent microRNA in vascular smooth muscle cells (VSMC) and a

master regulator of vascular smooth muscle cell fate. Increases in miR-145 provide a previously unrecognized mediator of vitamin D protection against vascular injury with aging and kidney disease progression, as nephron reduction and hyperphosphatemia decrease aortic miR-145 content [229]. Importantly, miR145 overexpression increases, and its silencing reduces the expression of alpha-actin and markers of the integrity of the arterial elastin layer in the absence of pro-calcifying signals, supporting the relevance of vitamin D induction of miR-145 in maintaining proper arterial contractility and preventing osteogenic differentiation even under non-calcifying stimuli [115]. Reduced VSMC miR-145 promotes loss of the contractile phenotype with de-differentiation toward a proliferative, migratory phenotype causing a blunted hypertensive response, arterial thickening, restenosis, and atherosclerosis [230–233].

Hyperphosphatemia, a risk factor for VC and cardiovascular mortality in individuals with normal renal function [234], also reduces miR-145 content in normal aortas [235]. In turn, miR-145 downregulates the osterix gene [236], an inducer of bone mineralization [237], and directly targets the transcription factor Krüppel-like factor 4 (KLF4), which controls the expression of osteogenic Runx2 [238–240], thus supporting a role for miR145 reductions in vitamin D deficiency- or hyperphosphate-mia-driven vascular calcification. Importantly, combined therapy with 25(OH)D and paricalcitol in a mouse model of established uremia was sufficient to prevent reductions of aortic miR-145, thereby attenuating decreases in  $\alpha$ -actin and increases in Runx2 despite severe hyperphosphatemia [115].

In addition to its anti-hypertensive properties, the integrity of the vitamin D endocrine system is essential to ensure immune protection from bacterial and viral infections, minimize progression of autoimmune disorders, and avoid excessive inflammation [241]. The 1,25(OH)<sub>2</sub>D/VDR complex influences innate and acquired immunity through multiple mechanisms including decreasing the antigenicity of antigen-presenting cells, downregulating the production of pro-fibrotic and pro-inflammatory Th1 cytokines, enhancing the production of anti-inflammatory Th2 cytokines, shifting T cell polarization toward a Th2/regulatory phenotype, and stimulating T regulatory lymphocyte development [1,241] (see Chapter 96). 1,25(OH)<sub>2</sub>D inhibition of Skp2 expression may partly explain the maintenance of T regs [242] and the blockage of autophagic flow driven by the cell invasion by Middle East respiratory syndrome coronavirus (MERS-CoV) [243]. 1,25(OH)<sub>2</sub>D immune regulatory properties confer protection not only from inflammation-driven multiple organ damage but also from inflammation-driven reductions of renal klotho that accelerate CKD progression.

In CKD, increased ADAM17-mediated release of TNF $\alpha$  to the circulation is a main determinant of the degree of systemic inflammation and renal and cardiovascular damage, as demonstrated by a higher degree of cardiovascular mortality in individuals with normal renal function carrying a polymorphism of ADAM17 that results in a mild increase in TNF $\alpha$  release [244]. Furthermore, specific deletion of ADAM17 in myeloid cells is sufficient to markedly reduce mortality rates in a rat model of LPS-induced sepsis [245]. Accordingly, in hemodialysis patients, circulating mononuclear cells express higher levels of ADAM17 and higher serum levels of TNF $\alpha$ , which can be reduced by combined vitamin D and 1,25(OH)<sub>2</sub>D (analog) administration [246]. Significantly, similar to the impaired 25(OH)D uptake in renal proximal tubular cells with advancing CKD, peripheral blood mononuclear cells from hemodialysis patients also have a 40% reduced capacity for 25(OH)D uptake. Surprisingly, even when mononuclear cells do not express megalin, the defective uptake was corrected with 1,25(OH)<sub>2</sub>D administration [96].

Finally, as indicated earlier, the induction of ADAM17 activity at the cell membrane induced by elevations by circulating angiotensin II provides a causal link between hypertension and inflammation, two highly interrelated processes. Importantly, as depicted in Fig. 79.9, a novel causal link between inflammation-driven hypertension has been identified recently. In mice, while the absence of monocyte lineage prevents angiotensin II–driven hypertension [247], the over-activation of the renin–angiotensin system results in renal and vascular accumulation of pro-inflammatory macrophages, resulting in increased oxidative stress and its associated tissue damage. In the vasculature, hypertension-induced macrophage infiltration drives nitric oxide scavenging causing reductions in renal blood flow [248], which in turn induces renin secretion by juxtaglomerular cells [248]. However, until recently, there was no evidence for immune cell–induced hypertension or its modulation by vitamin D. Studies from the Bernal-Mizrachi laboratory have demonstrated that increases in ER stress in response to vitamin D deficiency are sufficient to cause renin–dependent hypertension through the secretion of micro-RNA 106b-5p that enables a direct communication between innate immune cells and juxtaglomerular cells [116]. Importantly, the miR106b-5p link between inflammatory immune cells and renin secretion by juxtaglomerular cells can be prevented by the 1,25(OH)<sub>2</sub>D/VDR complex.

In summary, the integrity of the vitamin D endocrine system protects from CKD progression through direct inhibition of renal klotho reductions, maintenance of the FGF23/sklotho axis, attenuation of systemic inflammation, and hypertension that ameliorate CKD-induced excess of circulating FGF23. Maintenance of renal klotho

ensures the reduction of the pro-aging actions of phosphate retention, as well as the longevity properties of klotho-mediated induction of renal auto-phagic flow and of klotho and klotho-derived peptide inhibition of Wnt/ $\beta$ -catenin signaling to attenuate the progression of diabetes to diabetic nephropathy, as well as novel actions of the FGF23/sklotho/FGFR1 ternary complex to counteract FGF23 pathological actions in the heart. However, circulating soluble klotho is not an accurate marker of renal klotho reductions.

Vitamin D-mediated suppression of hypertension has a dual impact on CKD progression by reducing angiotensin II-driven renal damage and attenuating the reductions in renal klotho. The former is achieved through the maintenance of an adequate balance between pro-hypertensive (renin and ADAM17) and anti-hypertensive signals (ACE2). Increases in circulating ACE2 levels may provide an accurate measurement of increased ADAM17 activity and the cardiovascular risk associated with reductions in ACE2 expression at the cell membrane in CKD, which may be corrected with 1,25(OH)<sub>2</sub>D (analog) therapy. Finally, 1,25(OH)<sub>2</sub>D-mediated reduction of macrophage miR106b-5p release into the circulation provides the first causal link between macrophage ER stress activation and the induction of renin-dependent hypertension.

Measurements of miR106b, circulating ACE2, angiotensin II, or angiotensin 1–7 levels rather than circulating 25(OH)D levels may help improve vitamin D supplementation strategies to overcome the tremendous variability among individuals in their capacity not only for local 1,25(OH)<sub>2</sub>D production, but also for the local bio-activation of vitamin D to 25(OH)D in tissues bearing 25-hydroxylases that limit vitamin D renal and cardiovascular protection.

### **11. Progress to improve current recommendations for the evaluation of vitamin D status and for the design of safe and effective vitamin D interventions**

This section presents an update of recent international efforts to present physicians with evidence-based clinical practice recommendations to comply with the 2017 KDIGO guidelines to correct vitamin D deficiency in CKD prior to the initiation of 1,25(OH)<sub>2</sub>D (analog) interventions to treat SHPT and ameliorate cardiovascular risks [111].

The National Kidney Foundation (NKF) gathered a panel of experts at a Controversy Conference on Vitamin D in CKD3-4 in 2018 to help resolve current controversies on the diagnosis of vitamin D deficiency/insufficiency and provide definitive indications for optimal therapeutic intervention for its correction to control

elevations in serum PTH [249]. Briefly, the consensus was to consider (1) Serum 25(OH)D concentrations above 20 ng/mL in these patients as “adequate” vitamin D levels, with no need for supplementation; (2) Serum 25(OH)D below 15 ng/mL as an indication of vitamin D deficiency that requires supplementation regardless of serum PTH, and (3) Serum 25(OH)D levels in the 15–20 ng/mL range as an indicator of vitamin D insufficiency, with no need for supplementation unless there is evidence of counter-regulatory hormone activity (increased PTH or FGF23).

Similar recommendations emerged from a CKD-MBD working group from the European Society of Pediatric Nephrology for CKD2-5 and dialysis patients (less than 18 years old), who are more prone to nutritional rickets, poor bone growth, and poor overall bone health [250]. These recommendations were applicable also for kidney transplant recipients, who have a higher propensity to bone abnormalities due to their prior CKD, the degree of SHPT after transplant, and the immunosuppressive therapy. In children, normal 25(OH)D has been shown sufficient to delay the onset of SHPT and to prevent nutritional rickets. Therefore, this group recommended supplementation to patients with vitamin D deficiency (25(OH)D < 20 ng/mL) or vitamin D insufficiency (25(OH)D > 20 ng/mL, < 30 ng/mL) with ergocalciferol or cholecalciferol to achieve normal 25(OH)D (> 30 ng/mL). Importantly, supplementation strategies should be adjusted by age and baseline vitamin D status.

Due to the high variability between 25(OH)D assays, the European working group also recommends the use of external quality control strategies to ensure the accuracy of 25(OH)D<sub>2</sub> or 25(OH)D<sub>3</sub> measurements, as well as the assessment of serum and urinary calcium to minimize the risks for vitamin D toxicity from hypercalcemia, hypercalciuria, and nephrocalcinosis. In case of children with proteinuria, the group also recommended to evaluate bioavailable serum 25(OH)D by correcting for serum DBP and albumin levels [250].

Ergocalciferol, cholecalciferol, 25(OH)D, and extended release 25(OH)D are the compounds currently available for vitamin D supplementation. Ergocalciferol and cholecalciferol are equally effective at increasing serum 25(OH)D levels when administered daily [251]. The shorter half-life of 25(OH)D<sub>2</sub> compared with that of 25(OH)D<sub>3</sub> requires an increased frequency of D<sub>2</sub> dosage to compensate for its decay below basal levels by 2 weeks after bolus ergocalciferol administration [252]. High bolus doses of either compound should be avoided, not only for their higher risk of toxicity, but also because the rates of conversion of vitamin D to 25(OH)D decrease for dosages above 4000 IU [41].

The extended-release form of 25(OH)D (caldiol, ERC) has been available in the United States since 2016, and 25(OH)D has been the main compound for

the correction of vitamin D deficiency in Spain. Both compounds are extremely useful for the rapid correction of serum 25(OH)D, particularly in individuals with hepatic dysfunction or undergoing treatment with anti-epileptic medications with impaired conversion of vitamin D to 25(OH)D in the liver [253,254]. The efficacy to rapidly augment serum 25(OH)D may better counteract the impaired substrate availability to renal or parathyroid  $1\alpha$ -hydroxylases [85,92]. However, important safety considerations include the higher potency of 25(OH)D to induce intestinal calcium absorption and 1,25(OH)<sub>2</sub>D catabolism, even in individuals with normal renal function.

The recent randomized clinical trial in CKD3–4 patients demonstrating that extended release calcifediol (ERC) administration safely suppressed PTH only after achieving serum 25(OH)D concentrations higher than 50 ng/mL suggested that current targets for vitamin D repletion are too low [255]. However, these high concentrations were shown to increase the risk of mortality in women with normal kidney function and cause symptomatic toxicity in children with hypercalcemia and suppressed PTH.

Undoubtedly, it is unclear whether a supplementation strategy efficacious to correct vitamin D deficiency and suppress PTH will improve bone mineral density and bone strength and reduce fragility fractures. Indeed, in men and women 70 years or older with normal renal function and a prior fall, cholecalciferol supplementation of 24,000 IU monthly improves the incidence of non-vertebral fractures and frequency of falls due to improved muscular function and physical activity [256]. However, cholecalciferol dosage of 60,000 IU, or of 24,000 IU in combination with 300 ug of 25(OH)D reverses the benefits of correcting vitamin D deficiency causing an increase in the number of falls and impaired suppression of PTH. Most likely, induction of 1,25(OH)<sub>2</sub>D catabolism by the excess of 25(OH)D mediates these undesired actions.

To better control for an adverse impact on bone from vitamin D supplementation, both international working groups suggested to improve current evaluation of bone turnover (bone-specific and total alkaline phosphatase, serum collagen 1C telopeptide, intact procollagen type 1-terminal propeptide) to assess the adequacy of vitamin D interventions without bone biopsies.

Changes in proteinuria with vitamin D supplementation could provide a surrogate marker of the degree of CKD progression. Thus, the NKF Controversy Conference also suggested the implementation of intermediate end point trials to identify populations of responders, effective agents, and optimal doses before moving to clinical outcomes studies. It is also recommended to personalize vitamin D interventions using 24,25(OH)2D3/25(OH)D ratios and 1,25(OH)D/25(OH)D ratios,

serum PTH and FGF23 as surrogate markers of the abnormalities in the regulation of renal 1-hydroxylase and 24-hydroxylase activity with CKD progression.

In contrast to vitamin D supplementation strategies to control SHPT in CKD, there are precise recommendations for 1,25(OH)<sub>2</sub>D (analog) replacement therapy according to serum PTH, calcium, and phosphate levels as well as CKD stages. Therapeutic agents include 1,25(OH)<sub>2</sub>D, two prohormones  $1\alpha$ (OH)D<sub>2</sub> and  $1\alpha$ (OH)D<sub>3</sub>, which are activated to 1,25(OH)<sub>2</sub>D by the 25-hydroxylation by hepatic hydroxylases, and three analogs. The analogs include paricalcitol (19nor, 1,25-dihydroxyD<sub>2</sub>), maxacalcitol (22-oxa-1,25(OH)<sub>2</sub>D), and fale1,25(OH)<sub>2</sub>D (hexafluorinated 1,25(OH)<sub>2</sub>D). Nevertheless, individualized treatment plans to control SHPT with 1,25(OH)<sub>2</sub>D (analog) should be established and closely monitored to ensure the best possible outcomes while avoiding potential risks such as alterations in calcium and phosphate levels as well as insufficient inhibition or over-suppression of PTH.

Importantly, despite the survival benefits initially reported for paricalcitol over 1,25(OH)<sub>2</sub>D in hemodialysis patients and in numerous studies in animal models of CKD, at present there are no conclusive studies supporting the use of 1,25(OH)<sub>2</sub>D or analogs to improve survival.

## 12. Summary points

- In the normal kidney renal tubular cell, the highly coordinated, cell-specific genomic regulation of CYP27B1 and CYP24A1 by PTH, FGF23, 1,25(OH)<sub>2</sub>D, calcium, and phosphate ensures the maintenance of serum 1,25(OH)<sub>2</sub>D and 25(OH)D levels within normal levels.
- In CKD, vitamin D–mediated suppression of systemic inflammation contributes to the maintenance of renal and circulating anti-aging klotho and ameliorates the adverse impact of cytokine-induced elevations in renal, spleen, and immune cell FGF23 production.
- In CKD, vitamin D–mediated suppression of FGFR4 expression and induction of the klotho gene may counteract FGF23/FGFR4-driven LVH and the resistance to FGF23 phosphaturic action by facilitating ternary FGF23/s-klotho/FGFR1 complex formation.
- Small klotho peptides effectively control  $\beta$ -catenin activation by mimicking s-klotho to attenuate the progression of diabetic nephropathy.
- Defective vitamin D signaling in monocyte–macrophages increases the susceptibility of CKD patients to bacterial and viral infections and hypertension.

- In CKD, the correction of vitamin D deficiency with cholecalciferol or ergocalciferol supplementation should be personalized according to surrogate markers of vitamin D activation and catabolism and directed to improve clinical outcomes regardless of circulating 25(OH)D levels.

# Vitamin D and kidney stones

*Mansi Mehta and David S. Goldfarb*

NYU Langone Health and NYU Grossman School of Medicine, and New York Harbor VA Healthcare System, New York, NY, United States

## OBJECTIVES

- Understand vitamin D metabolism as it relates to urinary calcium excretion and calcium kidney stone formation.
- Explore the relationship between vitamin D supplementation and kidney stone formation.
- Understand current approaches to the prevention and treatment of bone mineral disease in calcium kidney stone formers.

## 1. Introduction

Vitamin D is integral to calcium and phosphorus homeostasis and to bone metabolism (see Chapters 16–18). Its deficiency is associated with low bone mass and secondary hyperparathyroidism (see Chapters 62 and 63). The formation of calcium kidney stones is associated with higher urinary calcium concentrations, which may be increased by higher circulating levels of 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ). The potential risk that  $1,25(\text{OH})_2\text{D}$  can increase urinary calcium excretion, and thereby lithogenesis, has made clinicians hesitant to treat vitamin D deficiency in patients with a history of calcium stones. Treatment with vitamin D is commonly listed as a risk factor for calcium kidney stone disease [1]. However, observational data supporting this putative relationship are not compelling. The relationship between vitamin D and calcium stones remains controversial. Currently, there is no clear contraindication to treating vitamin D deficiency in patients with calcium kidney stones. However, whether screening for

vitamin D deficiency, followed by supplementation, in such patients (or in the general population) is even worthwhile is also not established.

## 2. Calcium kidney stones

Kidney stone disease is a major clinical and economic health burden with an estimated prevalence of about 10% in the US population. Its prevalence has increased in the United States over the past 30 years with a cost burden of more than \$5 billion annually in the United States [2,3]. Kidney stones are recurrent: after passage of a first stone, the risk of recurrence is 40% at 5 years and 75% at 20 years.

The most common type of kidney stones are composed of calcium, and they comprise 85% of all stones. Calcium stones are made of calcium oxalate (50%), calcium phosphate (~5%–10%), and a mixture of both (45%) [4]. They are associated with other chronic conditions such as hypertension, cardiovascular disease, metabolic syndrome, and diabetes mellitus. Evidence suggests that dietary habits, such as diets high in sodium and animal protein with fewer fruits and vegetables, are common risk factors for kidney stone formation and link stones with the aforementioned chronic diseases. Calcium stones are also commonly associated with bone mineral loss and fractures [5,6].

Calcium stone formation is a complex physiological process. The key factors are high urine supersaturation, crystallization, growth, and aggregation. In calcium stone formers, an imbalance between excretion of calcium, oxalate, citrate, and water results in crystal precipitation and aggregation [1]. Higher urine calcium excretion is a significant risk factor for calcium stone

formation. Since most stones contain calcium, and because higher urine calcium excretion has been associated with the formation of stones, a traditional treatment approach was dietary calcium restriction. However, this approach has now been out of favor for nearly 30 years. Patients with greater dietary calcium intake have fewer stones [7,8]. Patients treated with higher dietary calcium intake (and with lower intake of animal protein, sodium, and oxalate), compared with patients challenged by a low-calcium diet, had fewer stones [9]. Such out-of-date calcium-restricted diets would be expected to be associated with loss of significantly more calcium in the urine than control patients and result in a reduction in bone mineral density and increased rate of fracture [10]. Data have also suggested that a higher dietary calcium intake may decrease the incidence of symptomatic kidney stones and bone loss. The effect of higher dietary calcium intake on stone prevention is attributed to the binding of ingested calcium to oxalate in the intestinal lumen, leading to reduced intestinal oxalate absorption leading to lower urinary saturation of calcium oxalate [11].

### 3. Vitamin D metabolism

Vitamin D, obtained from diet or produced by skin, first undergoes hydroxylation in the liver by 25-hydroxylase (*CYP2PR1*) to yield 25-hydroxyvitamin D3 (25(OH)D), which is then further hydroxylated, primarily in the kidney, by 25(OH)D-1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase or *CYP27B1*) to produce bioactive form 1,25(OH)<sub>2</sub>D (see Chapter 4). The renal production of 1,25(OH)<sub>2</sub>D by 1 $\alpha$ -OHase is tightly regulated by parathyroid hormone (PTH), calcium, and phosphorus levels and by 1,25(OH)<sub>2</sub>D itself (see Chapter 8). The receptor for 1,25(OH)<sub>2</sub>D, vitamin D receptor (VDR), is located in the cell nucleus and found in most tissues, such as intestine, bones, kidneys, muscles, and organs of immune system (see Chapters 10–13).

The most important role of 1,25(OH)<sub>2</sub>D is the promotion of intestinal absorption of calcium. Decreased levels of 1,25(OH)<sub>2</sub>D diminish intestinal calcium absorption resulting in increased serum levels of PTH causing secondary hyperparathyroidism. Secondary hyperparathyroidism maintains normal serum calcium levels by increasing renal calcium resorption and thereby reducing 24 h urinary calcium excretion. 1,25(OH)<sub>2</sub>D also directly inhibits synthesis of PTH, regulates renal and intestinal phosphate absorption, and regulates osteoblastic function and bone resorption by stimulating fibroblast growth factor 23 (FGF23) [12] (see Chapter 19).

The enzyme 24-hydroxylase (24-OHase or *CYP24A1*) deactivates 1,25(OH)<sub>2</sub>D, forming 1,24,25-trihydroxy vitamin D, leading eventually to the production of calcitric acid [13]. In addition, *CYP24A1* converts 25(OH)D

to 24,25-dihydroxyvitamin D (24,25(OH)<sub>2</sub>D), which prevents its conversion to the active 1,25(OH)<sub>2</sub>D (see Chapter 5). Both calcium and 1,25(OH)<sub>2</sub>D inhibit the activity of 1 $\alpha$ -OHase. Therefore, the potential toxic effect of vitamin D supplementation to increase urinary calcium excretion may be mitigated: the effects of an increase in serum calcium and an increase in active vitamin D inhibit increases in 1 $\alpha$ -OHase activity [14]. As shown in Fig. 80.1, tight regulatory mechanisms are in place to control intestinal calcium absorption and limit increased urinary calcium excretion with vitamin D supplementation [15]. 1 $\alpha$ -OHase is upregulated by PTH, hypocalcemia, and hypophosphatemia and downregulated by 1,25(OH)<sub>2</sub>D. The deactivating enzyme, 24-OHase, is upregulated to cause degradation of 1,25(OH)<sub>2</sub>D and prevent hypercalcemia. Genetic variations in *CYP24A1* may explain why some calcium stone formers have elevated 1,25(OH)<sub>2</sub>D levels when supplemented with vitamin D [16].

### 4. Idiopathic hypercalciuria

Idiopathic hypercalciuria (IH) is a traditional term used for the frequent occurrence of higher urine calcium excretion in stone formers, the cause of which remains poorly elucidated. Even the term “hypercalciuria” is poorly defined, since no threshold for pathologic calcium excretion is widely recognized [17]. Patients with IH have an elevated urinary calcium excretion, are normocalcemic, and often have relatively elevated 1,25(OH)<sub>2</sub>D levels with normal PTH [18]. Calcium stone formers have higher urinary calcium excretion compared with nonstone formers regardless of dietary calcium intake. The distinction between “absorptive” and “renal” hypercalciuria is no longer considered appropriate, as features of both phenotypes are present in most such patients [19]. Similarly, low-calcium diets are not considered appropriate for the patients once called “absorptive” hypercalciuria. Higher urine calcium excretion has also been associated with low bone mineral density and fractures [5].

Observations suggest that the pathogenesis is due to a primary increase in intestinal calcium absorption and a primary overproduction of 1,25(OH)<sub>2</sub>D. Consistent with that hypothesis, studies have confirmed that on average, serum 1,25(OH)<sub>2</sub>D levels are higher in IH, and most interestingly, the changes in calcium metabolism can be induced by the administration of small doses of 1,25(OH)<sub>2</sub>D to healthy volunteers [20,21]. A prospective study following males over 12 years revealed higher plasma 1,25(OH)<sub>2</sub>D, even in ranges considered normal, and was independently associated with a higher risk of symptomatic kidney stones [22]. In fact, the mean value for serum 25(OH)D was in the normal range. The authors found that the association of serum 1,25(OH)<sub>2</sub>D with renal stone risk was

**FIGURE 80.1** Vitamin D metabolic pathways and activating and inhibiting factors associated with kidney stone formation.

independent of calcium intake and plasma levels of PTH, phosphorus, and 25(OH)D, all modulators of 1 $\alpha$ -OHase. In other words, the basis for these marginally higher values was uncertain. In addition, higher FGF23 levels were also associated with risk, although of borderline statistical significance, and of uncertain pathophysiology. Not all studies have been able to demonstrate an association between elevated serum 25(OH)D, in the range of 20–100 ng/mL, and kidney stones [23].

Two genes, soluble adenylate cyclase 10 (*ADCY10*) and vitamin D receptor (*VDR*), have been implicated in IH. Unlike *VDR*, the function of *ADCY10*, a bicarbonate-sensitive enzyme, and its link to urine calcium excretion, is not understood [24–26]. Likewise, the genetic hypercalciuric stone-forming rat (GHS) has been bred for higher urinary calcium excretion [27]. While the genes responsible for the elevated urinary calcium excretion remain uncertain, the model does recapitulate the human IH phenotype. Among the characteristics of this stone-forming animal model, elevated *VDR* expression is demonstrated in the intestinal mucosa, renal tubules, and bone cells [27]. These findings support the hypothesis that *VDR* may play a role in the human form of higher urine calcium as well. The GHS rat also recapitulates the human bone phenotype of lower bone mineral density and lower bone strength [28].

Inactivating mutations in *CYP24A1* lead to an inability to deactivate calcitriol. These mutations were first demonstrated in infantile hypercalcemia, an

inherited autosomal recessive disorder characterized by hypercalcemia and nephrocalcinosis (see Chapter 69). Because of the failure to inactivate vitamin D, PTH is suppressed and 1,25(OH)<sub>2</sub>D is elevated. Vitamin D supplementation was first implicated in the pathogenesis of this disorder during the epidemic of infantile hypercalcemia and increased doses of vitamin D in infant formula in the United Kingdom [14]. Less severe cases, presenting in adults, with stones, with or without hypercalcemia, are seen without significant vitamin D supplementation [29,30]. Typically, patients have high serum 1,25(OH)<sub>2</sub>D and low levels of 24,25(OH)<sub>2</sub>D. Nephrocalcinosis may lead to chronic kidney disease. The prevalence of *CYP24A1* mutations may account for a larger proportion of calcium stones among adults as well. In fact, this group of patients may account for some significant, but undefined proportion of patients, who are susceptible to kidney stones, particularly as a consequence of vitamin D supplementation. This finding is suggested by genome-wide association studies that do show that the *CYP24A1*-associated locus correlates with serum calcium concentration and the number of nephrolithiasis episodes [31]. These patients have been treated with ketoconazole and fluconazole, which inhibit 1 $\alpha$ -OHase, reducing serum levels of 1,25(OH)<sub>2</sub>D [32]. In addition, rifampin, the antituberculosis antibiotic, has been used successfully to inactivate vitamin D via induction of another catabolic enzyme *CYP3A4* [23] (see Chapter 67).

## 5. Vitamin D supplementation and kidney stone risk

Observational studies of individuals without kidney stones taking vitamin D supplements have not convincingly demonstrated that such supplementation is associated with increased urinary calcium excretion or increased rates of kidney stones.

Supplemental administration of vitamin D to attain circulating levels of 25(OH)D greater than 32 ng/mL in a group of 138 participants did not significantly increase urinary calcium excretion [33]. One prevalent limitation of such studies is that those in whom vitamin D is given without calcium supplementation are few in number, so that the role of vitamin D per se is unclear. Among stone formers as well, vitamin D repletion for a limited duration does not appear to adversely affect overall 24-h urine calcium excretion in individuals with vitamin D deficiency or insufficiency. A subset of individuals may have an increase in urinary calcium excretion, but this may be attributed to dietary habits such as high sodium and protein intake [33].

Two recent studies have demonstrated no statistically significant risk with vitamin D supplementation and kidney stone formation. In one study, 29 participants with a history of nephrolithiasis, urinary calcium excretion between 150 and 400 mg/d, and a serum 25(OH)D level less than 30 ng/mL were given oral ergocalciferol at a dose of 50,000 IU/week for 8 weeks. While serum 25(OH)D levels increased after repletion, mean 24-h urinary calcium excretion did not. Although 11 participants did have an increase in their urinary calcium excretion, urinary sodium excretion was also increased suggesting a dietary effect [33]. In the largest observational study to date on vitamin D and kidney stones, a prospective analysis of nearly 200,000 male and female participants from 3 well-characterized cohorts, Health Professionals Follow-up Study and Nurses' Health Study I and II, found no statistically significant association between vitamin D intake and risk of stones in men or women after multivariate adjustment (for different variables, including use of calcium supplements) [34]. Few in the cohort had vitamin D intake greater than 2000U daily, and the study concluded that vitamin D in "typical amounts" is not associated with increased risk of kidney stone formation. Among healthy postmenopausal women, calcium with vitamin D supplementation resulted in a small but significant improvement in hip bone density but did not significantly reduce hip fracture risk with an increased reported risk of kidney stones [35]. This is the only known study to report an increased risk of kidney stones after the administration of vitamin D. Again, this increased risk could be explained by the concomitant use of vitamin D with

elemental calcium, which is known to increase urinary calcium excretion. The US Preventative Services Task Force has found insufficient evidence to recommend screening in men and postmenopausal women and recommends against daily supplementation of 400IU or less of vitamin D and 1000 mg or less of calcium for the primary prevention of fractures in postmenopausal women. To date, the overall evidence regarding the effect of vitamin D in causing stones has been largely unconvincing.

## 6. Conclusions

Because vitamin D deficiency has been associated with cardiovascular disease, fractures, colorectal cancer, diabetes, depression, and death, the hope had been for vitamin D supplementation to reverse these adverse outcomes. However, randomized controlled trials have shown that vitamin D supplementation has low to no benefit on mortality, bone mineral density, and incidence of falls and fractures, diabetes, cancer, and cardiovascular disease [36]. In fact, recommendations now are relatively neutral, if not negative regarding vitamin D screening [36]. Compounding the difficulty of screening and interpretation of results are the variability between assay methods and the prevalent seasonal variation in 25(OH)D levels [37].

There is also a lack consensus about the definition of 25(OH)D deficiency and repletion regimens. As a result, the US Preventative Services Task Force recommends against the routine screening of vitamin D in asymptomatic adults who "are not known to have signs or symptoms of vitamin D deficiency or conditions for which vitamin D treatment is recommended" [38]. With regard to bone health, symptomatic patients with nontraumatic fractures, kidney dysfunction or malabsorptive disorders, including kidney stone patients, require intervention. A history of kidney stones, itself, is independently associated with higher risk of wrist fracture and a risk for osteoporosis [39]. Workup for metabolic abnormalities in kidney stone patients has also revealed inadequate vitamin D levels, making this population prone to being prescribed vitamin D supplementation [40]. However, as the evidence for vitamin D supplementation remains unsatisfactory, how can we treat bone mineral disease in at-risk stone formers? A prescription for dietary alteration is recommended. The Borghi diet, which recommends increased calcium intake and restricted sodium and animal protein intake, has been proven in a randomized clinical trial to prevent calcium stones [9]. Nondietary calcium supplementation, which frequently accompanies vitamin D supplementation, is positively associated with kidney stone

formation, while the inverse has been shown to be true for dietary calcium and kidney stone risk [8]. Calcium when administered as calcium citrate instead of calcium carbonate, or the timing of supplements with meals, may decrease the risk of lithogenicity when supplementation is required [41].

Thiazides are well established for the prevention of calcium stones and are recommended by both the American Urological Association and European Association of Urology. A metaanalysis revealed a 47% reduction in relative risk of calcium stone recurrence with thiazide use [42]. Thiazides increase calcium absorption in the distal tubule and indirectly in the proximal tubule reducing urinary calcium excretion. As a result, retained calcium increases bone mineral density and leads to a reported 10% reduction in fractures [43].

Hypocitraturia is a common finding in the workup of metabolic abnormalities in stone formers. Chronic acid loads in the form of high-protein diets, which reduce urinary pH and citrate excretion, are not only associated with kidney stone formation, but also with decreased bone mass [44]. The administration of oral potassium citrate increases urinary citrate and reduces calcium excretion, thereby reducing the risk of kidney stone formation, and has also been shown to increase bone mass in postmenopausal women [45].

Bisphosphonates are a well-established therapy for osteoporosis. In patients with low bone density, bisphosphonate use is associated with decreased 24-h urinary calcium excretion [46], and a lower incidence of kidney stones [47].

## 7. Summary points

- Vitamin D is integral to calcium balance and maintenance of bone health. Widespread screening for vitamin D deficiency and supplementation does not appear to have contributed to kidney stone prevalence in the general population. Vitamin D supplementation may increase stone risk in patients with underlying CYP24A1 mutations.
- There is no clear contraindication or benefit to treating vitamin D deficiency and bone mineral disease in patients with calcium kidney stones. Alterations in diet, thiazides, and citrate administration are instead well-established therapies for the prevention of calcium kidney stones.

# Hypercalcemia due to vitamin D toxicity

*Yasaman Motlaghzadeh<sup>1</sup>, John P. Bilezikian<sup>2</sup> and Deborah E. Sellmeyer<sup>1</sup>*

<sup>1</sup>Division of Endocrinology, Gerontology and Metabolism, Stanford University School of Medicine, Palo Alto, CA, United States <sup>2</sup>Division of Endocrinology, Vagelos College of Physicians and Surgeons, Columbia University, New York, NY, United States

## OBJECTIVES

- Categorize the types of vitamin D toxicity.
- Explain the different mechanisms of vitamin D toxicity.
- Describe the clinical manifestations of vitamin D toxicity.
- Review diagnosis and treatment measures of hypercalcemia due to vitamin D toxicity.

## 1. Introduction

Vitamin D toxicity is an uncommon cause of hypercalcemia. In the differential diagnosis of hypercalcemia, it is often buried amid a long list of other more and less common causes (Table 81.1). The most common causes of hypercalcemia, among the many etiologies, are primary hyperparathyroidism (PHPT) and hypercalcemia of malignancy, accounting for more than 90% of cases. Other causes of hypercalcemia, such as vitamin D toxicity, granulomatous disorders, cosmetic injections, thyrotoxicosis, adrenal insufficiency, milk alkali syndrome, medications, familial hypocalciuric hypercalcemia, and immobilization, comprise less than 10% of all causes of hypercalcemia. It is important to consider these uncommon etiologies when PHPT and malignancy have been ruled out [1]. In these settings, vitamin D toxicity becomes an important consideration in the differential diagnosis of hypercalcemia. This chapter reviews the various forms of vitamin D toxicity,

mechanisms of hypercalcemia due to vitamin D toxicity, clinical manifestations, diagnosis, and management.

## 2. Forms of exogenous vitamin D toxicity

Vitamin D toxicity can be life-threatening and associated with substantial morbidity, if not identified quickly. Hypervitaminosis D with hypercalcemia may be secondary to excessive intake of parent vitamin D, its metabolites 25-hydroxyvitamin D (25(OH)D), 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D<sub>3</sub>), or vitamin D analogs; to increased production of 25(OH)D or 1,25(OH)<sub>2</sub>D<sub>3</sub> from exogenous substrate; and even to topical applications of potent vitamin D analogs. Ergocalciferol is metabolized to 1,25(OH)<sub>2</sub>D<sub>3</sub>, however, since exogenous calcitriol is 1,25(OH)<sub>2</sub>D<sub>3</sub> and many supplements are vitamin D<sub>3</sub>, for simplicity purposes we use the nomenclature “1,25(OH)<sub>2</sub>D<sub>3</sub>” to refer to all forms of calcitriol.

### 2.1 Vitamin D and 25(OH)D toxicity

The most common etiology of vitamin D toxicity is inadvertent or improper oral use of pharmaceutical preparations. Excessive ingestion of vitamin D, usually much greater than 10,000 IU per day, can cause vitamin D intoxication that is recognized by markedly elevated levels of 25(OH)D (typically >200 ng/mL) in association with levels of 1,25(OH)<sub>2</sub>D<sub>3</sub> that are normal or only slightly elevated. Hyperphosphatemia can be a clue to the etiology of the vitamin D-mediated hypercalcemia since parathyroid hormone (PTH)-related and PTH-related peptide (PTHrP)-related disorders usually are

**TABLE 81.1** Differential diagnosis of hypercalcemia.

Primary hyperparathyroidism
Sporadic (adenoma, hyperplasia, or carcinoma)
Familial
Isolated
Cystic
Multiple endocrine neoplasia type I or II
Malignancy
Parathyroid hormone-related protein
Excess production of 1,25-dihydroxyvitamin D
Other factors (cytokines, growth factors)
Disorders of vitamin D
Exogenous vitamin D toxicity – parent D compound, 25(OH)D, 1,25(OH)D, vitamin D analogs
Endogenous production of 25-hydroxyvitamin D (may be seen in Williams syndrome)
Endogenous production of 1,25-dihydroxyvitamin D
Granulomatous diseases
a. Sarcoidosis
b. Tuberculosis
c. Histoplasmosis
d. Coccidioidomycosis
e. Leprosy
f. Others
Foreign body inflammatory reactions
Lymphoma
Non-parathyroid endocrine disorders
Thyrotoxicosis
Pheochromocytoma
Acute adrenal insufficiency
Vasoactive intestinal polypeptide hormone-producing tumor (VIPoma)
Medications
Thiazide diuretics
Lithium
Estrogens/antiestrogens, testosterone in breast cancer
Milk-alkali syndrome
Vitamin A toxicity
Familial hypocalciuric hypercalcemia
Immobilization
Parenteral nutrition
Aluminum excess
Acute and chronic renal disease

associated with normal or reduced serum phosphate levels [2–4]. However, it is important to recognize that hyperphosphatemia is not always seen in vitamin D toxicity, and there have been case reports of hypervitaminosis D–induced hypercalcemia associated with hypophosphatemia [5,6]. The usual setting of vitamin D toxicity is in its use as a therapy for hypocalcemic disorders such as hypoparathyroidism, pseudohypoparathyroidism, osteomalacia, or renal failure. Ingestion of excessive quantities of 25(OH)D, 1 $\alpha$ -hydroxyvitamin D, 1,25(OH)<sub>2</sub>D<sub>3</sub>, dihydrotachysterol, or exuberant use of the topical calcipotriene (Dovonex) for psoriasis can also cause vitamin D intoxication [7]. Health-conscious adults have been reported to ingest large doses of megavitamins from over-the-counter supplements, in amounts that may exceed 2 million IU of vitamin D daily

[8,9]. Cancer patients, in particular, have been observed to consume excess nutritional supplements such as calcium, vitamin D, and shark cartilage [10]. Hypercalcemia due to high doses of vitamin D use has also been reported in patients with multiple sclerosis [11–13]. Moreover, individuals have mistakenly ingested ergocalciferol 50,000 IU daily instead of more typical biweekly or monthly administration [6,14,15].

An over-the-counter supplement called Soladek has been implicated in vitamin D toxicity in a published case report and our own personal experience. This supplement, readily available in the Dominican Republic and in urban areas such as Manhattan, contains over 500,000 IU of vitamin D<sub>3</sub> and 120,000 IU of vitamin A per 5 mL vial. The package label for Soladek lists a number of indications for its use, including “hypo and avitaminosis, rickets, growth, dentition, lactation, fractures, infections, convalescence, protection and regeneration of certain epithelium (bronchial, glandular, ocular, cutaneous), corticotherapy, aging, pregnancy.” In the case report by Leu et al. [16], a 60-year-old woman with a medical history significant only for osteoarthritis presented with symptoms of hypercalcemia and a serum calcium of 15.2 mg/dL in the setting of recent Soladek use. Her 25(OH)D was >150 ng/mL with undetectable PTH and PTHrP levels. CT of the chest, abdomen, and pelvis, skeletal survey, and bone marrow biopsy were all negative for malignancy. However, colonoscopy revealed an anal squamous cell carcinoma that was resected. The patient’s hypercalcemia resolved after discontinuation of Soladek in addition to treatment with intravenous fluids, intermittent furosemide, and a single dose of pamidronate. In our own case series of nine patients, the majority of patients with hypercalcemia in the setting of Soladek use had a second condition that could have contributed to the development of hypercalcemia. No patient had previously experienced hypercalcemia before ingesting Soladek, however, indicating that the secondary condition was likely necessary, but not perhaps sufficient to produce hypercalcemia outside of excessive vitamin D supplementation from Soladek. Conversely, when the level of 25(OH) D is high but <200 ng/mL, it is advisable to seek another etiology as was the case in the series by Lowe et al. Hypercalcemia resolved in all patients after stopping the preparation [17].

It is commonly perceived that excessive sunlight exposure can be associated with vitamin D toxicity. However, studies have documented that full summer-long unprotected sun exposure cannot raise serum concentrations of 25(OH)D much more than 70–80 ng/mL. Whether one considers the changeable upper limits of normal for 25(OH)D at 50 or as high as 100 ng/mL, levels achieved by prolonged, unprotected sunlight exposure cannot by itself cause vitamin D toxicity (nl:

30–100) [18,19]. When dermal levels of vitamin D are high, vitamin D synthesis shunts to the production of inactive metabolites, which then can reenter the vitamin D synthesis pathway when dermal levels fall [20]. These recent observations help to document the widely held belief that sun alone cannot cause vitamin D toxicity. In situations where there is excessive conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D<sub>3</sub> such as in sarcoidosis or other granulomatous diseases; however, sun exposure can lead to hypercalcemia. While vitamin D is contained in fatty fishes (e.g., salmon, tuna) eggs, milk, and liver, the amounts are well under what would be needed to induce toxicity from these foods that naturally contain vitamin D. However, hypervitaminosis D has been associated with consumption of cow's milk when inadvertently fortified with massive concentrations of vitamin D. One investigation of eight patients manifesting symptoms of nausea, vomiting, weight loss, hyperirritability, or failure-to-thrive revealed markedly elevated mean concentrations of 25(OH)D of  $293 \pm 174$  ng/mL [4]. Analysis of the milk production facility at the local dairy revealed excessive vitamin D fortification of milk with up to 245,840 IU per liter (232,565 IU of vitamin D<sub>3</sub> per quart). Usual fortification of milk in the United States and Canada is 400 IU per quart. Milk is not fortified with vitamin D in most other parts of the world. In addition to milk, vitamin D fortification of natural foods includes plant-derived nondairy milks, breakfast cereals, yogurt, pasta, baked goods, fats, and orange juice [21]. Since the amount of vitamin D fortification is very modest, these foods are not generally suspected as a cause, bearing in mind of course the rare but important example of inadvertent toxic amounts of vitamin D fortification. In addition, industrial contamination of table sugar with vitamin D<sub>3</sub> and consequent severe vitamin D toxicity [25(OH)D level 623 ng/mL] has been reported [22].

Vitamin D<sub>2</sub> and vitamin D<sub>3</sub>, although used interchangeably in the treatment of metabolic bone diseases, may differ in toxic potential at higher doses. A recent metanalysis of 24 studies suggests that cholecalciferol is more effective at increasing vitamin D levels than ergocalciferol [23]. Armas et al. [24] estimated the potency of vitamin D<sub>3</sub> to be three times that of D<sub>2</sub> when given in larger, intermittent doses. These data also suggested that D<sub>2</sub> has a shorter duration of action and that it accelerates the metabolism of D<sub>3</sub> in human subjects. The differential effects of D<sub>2</sub> versus D<sub>3</sub> may be of clinical significance only when larger doses are given intermittently. At doses of 50,000 IU per month, supplementation with D<sub>2</sub> results in lower serum 25(OH)D levels compared with D<sub>3</sub>; however, when given as 1600 IU/day, serum 25(OH)D levels are not different during supplementation with either D<sub>2</sub> or D<sub>3</sub> [25]. The current, officially recommended dietary allowance (RDA) for

vitamin D is 400 IU for infants 0–12 months of age, 600 IU for men and women from aged 1–70 years (including during pregnancy and lactation), and 800 IU for men and women over age 70 years [26]. These guidelines are controversial with many experts and authoritative bodies calling for increases in these recommended amounts [27–31]. Although this chapter concerns itself with vitamin D toxicity, the recommendation to increase nutritional amounts of vitamin D is due to the high prevalence of vitamin D deficiency worldwide (see Chapter 54) [32,33]. If the RDA for vitamin is to increase in the future, it is possible that the potential for vitamin D toxicity will increase.

While primary hyperparathyroidism in the developed world is typically associated with mild hypercalcemia with few, if any, symptoms, the clinical picture of PHPT in the developing world, in which vitamin D deficiency is more common, has tended to be more severe with skeletal and renal complications. However, a systematic review by Kumar Yadav et al. in 2020 found a significant trend toward a milder form of disease presentation in developing countries in recent years [34].

Vitamin D deficiency in the setting of PHPT is associated with a more severe phenotype [35], and many studies show larger adenoma size, higher serum parathyroid hormone and alkaline phosphatase levels, lower bone mineral density, and higher rates of fracture [36–40]. Moreover, patients with vitamin D deficiency are at greater risk to develop hypocalcemia due to “hungry bone” syndrome after parathyroidectomy. Patients with PHPT and vitamin D deficiency present a therapeutic dilemma due to the potential risk of worsening hypercalcemia with vitamin D supplementation. Gray et al. [41] treated 21 patients with mild PHPT (serum calcium  $10.8 \pm 0.5$  mg/dL) and coexistent vitamin D deficiency [25(OH)D < 20 ng/mL] with ergocalciferol 50,000 IU weekly for 4 weeks followed by 50,000 IU monthly for the remainder of a year. With a rise in 25(OH)D levels, PTH levels fell by 25%. The reduction in PTH levels by approximately 25% suggests that this component of the elevated PTH was due not to the endogenously overactive parathyroid gland but rather to the secondary hyperparathyroidism of the vitamin D deficiency state. Unlike most tissues, the parathyroid gland is able to take up 25(OH)D bound to vitamin D-binding protein (DBP) via its expression of the megalin/cubilin complex (see Chapter 7 and Chapter 17). Additionally, within the parathyroid gland, the 1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase) is very active and, thus, able to synthesize 1,25(OH)<sub>2</sub>D<sub>3</sub> from the substrate, 25(OH)D in the parathyroid gland. This action would directly suppress PTH production [20]. In the study by Gray et al. [41], the serum calcium increased from 10.5 to 11.9 mg/dL in one patient, and in another patient, the 24-hour urinary calcium excretion increased to over

400 mg/day. In the remaining patients, there were no substantial changes in serum calcium or urinary calcium excretion. Tucci [42] subsequently showed no overall increase in serum calcium or urinary calcium excretion with doses of ergocalciferol 50,000 IU weekly for 8 weeks among 56 patients with primary hyperparathyroidism. Grubbs et al. [43] also showed no change in serum calcium with a dosing regimen of 50,000 IU weekly or twice weekly for a mean duration of 4 weeks in patients with primary hyperparathyroidism. However, 3 of 56 patients, and 6 of 112 patients, respectively, did show increases in serum calcium during the follow-up period. At surgery in these patients, parathyroid adenoma size was smaller in patients who had achieved vitamin D sufficiency prior to parathyroidectomy.

Isidro et al. [44] studied 27 patients with PHPT-administered calcifediol [25(OH)D<sub>3</sub>] supplementation of up to 960 IU daily and found no increase in serum calcium levels. However, up to one-third of patients became hypercalciuric. A more recent randomized, placebo-controlled study in 46 subjects with PHPT [45] showed that doses of 2800 IU daily were safe and effective. Subjects were treated for 26 weeks prior to parathyroidectomy with 25(OH)D levels increasing from 50 to 94 nmol/L in the treatment group and remaining unchanged in the placebo group;  $P < .001$ . The vitamin D-supplemented group also showed a significant decrease in PTH and bone resorption markers and a significant increase in lumbar spine bone density. There were no statistical differences between groups with regard to serum or urine calcium excretion. Loh et al. conducted a metaanalysis to assess the effects of vitamin D replacement in 547 patients with mild primary hyperparathyroidism and coexistent vitamin D deficiency. With vitamin D supplementation, serum 25(OH)D levels improved with no worsening of hypercalcemia or hypercalciuria [46]. Song et al. included 11 articles with a total of 388 patients and reported similar findings [47].

These studies, in the aggregate, make two points. First, vitamin D supplementation in PHPT seems to be well tolerated and does not lead, in general, to worsening hypercalcemia or hypercalciuria. Second, the studies highlight the importance of careful monitoring. In particular, high doses of vitamin D over a short period of time are not to be recommended. Guidelines from the Fourth International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism recommend supplementation of vitamin D starting at a dose of 800–1000 IU daily to achieve a minimum 25(OH)D level  $>20$  ng/mL [48]. The workshop participants noted that some experts recommend a goal of  $>30$  ng/mL in these patients.

The smallest dose of parent vitamin D (cholecalciferol or ergocalciferol) in healthy adults that can

produce toxicity and hypercalcemia is not known, but is clearly much higher than the RDA [26]. The current tolerable upper intake level (UL) recommended by the Food and Nutrition Board is 1000 IU daily for infants 0–6 months of age, 1500 IU daily for infants 7–12 months of age, 2500 IU daily for children 1–3 years of age, 3000 IU daily for children 4–8 years of age, and 4000 IU daily subsequently throughout life. Again, controversy exists regarding these guidelines [29–31]. Two small well-conducted clinical trials by Heaney et al. [49] and Barger-Lux et al. [2] showed that vitamin D<sub>3</sub> 10,000 IU daily for 8 and 20 weeks, respectively, did not cause an increase in serum calcium or any adverse effects in the combined cohort of 26 healthy men. In these subjects, mean 25(OH)D levels rose to 85 ng/mL ( $n = 10$ ) and 88 ng/mL ( $n = 16$ ) in the two studies, respectively. A review by Hathcock et al. [50] supports the selection of 10,000 IU daily as the UL based on these studies. Other studies of much shorter duration or concurrent treatment with prednisone and/or sodium fluoride have also shown that higher doses of vitamin D (up to 100,000 IU per day) were well tolerated. However, these vitamin D studies were not considered in their risk assessment due to short study lengths and potential confounders. In a randomized trial of calcium carbonate 1200 mg/day along with 10,000 IU vitamin D<sub>3</sub>/day (group 1) compared with the same dose of calcium plus 600 IU vitamin D<sub>3</sub>/day (group 2), the odds ratio for hypercalciuria was 3.6 in group 1 compared with group 2. However, the odds of developing hypercalcemia did not differ between the two groups [51].

Individuals manifest wide variations both in their response to hypercalcemic doses of vitamin D and in the duration of the effect. This variation in individual responsiveness might reflect differences in intestinal absorption and vitamin D metabolism, in the concentration of free vitamin D metabolites, in the rate of degradation of the metabolites and conversion to inactive metabolites, and in the capacity of storage sites for 25(OH)D [52]. Factors that enhance susceptibility to vitamin D toxicity and hypercalcemia include increased dietary calcium intake, reduced renal function, coadministration of vitamin A, presence of granulomatous disorders such as sarcoidosis, and genetic polymorphisms that render subjects more sensitive to vitamin D [4]. Hypercalciuria in hypervitaminosis D usually presents earlier than hypercalcemia, but it is easily missed for the obvious reason that urinary calcium is not routinely measured.

## 2.2 1,25-Dihydroxyvitamin D toxicity

The greater potency of 1,25(OH)<sub>2</sub>D<sub>3</sub> and its direct actions on target tissues, in addition to its ability to inhibit

PTH synthesis and secretion, has made  $1,25(\text{OH})_2\text{D}_3$  and its analogs useful agents in patients with renal osteodystrophy and secondary hyperparathyroidism [53] (see Chapter 79).  $1,25(\text{OH})_2\text{D}_3$  is also used for treatment of patients with hypoparathyroidism, a rare disorder characterized by hypocalcemia and low or deficient PTH concentrations [54].  $1,25(\text{OH})_2\text{D}_3$  has also been found to inhibit the growth of human cancer cells in vitro [55]. As  $1,25(\text{OH})_2\text{D}_3$  is increasingly recognized for its antiproliferative, prodifferentiating, and immunomodulatory actions, its potential therapeutic use is expanding [56]. Mechanisms associated with the hypercalcemia due to  $1,25(\text{OH})_2\text{D}_3$  are increased intestinal absorption of calcium and potentiation of osteoclastic activity in bone. Dosages of  $1,25(\text{OH})_2\text{D}_3$  considerably above  $0.75\text{ }\mu\text{g/day}$  have been associated with toxicity, whereas dosages at or below  $0.5\text{ }\mu\text{g/day}$  rarely result in toxicity. One investigation showed that over 90% of patients on doses of  $1,25(\text{OH})_2\text{D}_3$  between  $1.0$  and  $2.0\text{ }\mu\text{g/day}$  became hypercalcemic, and all had hypercalciuria when calcium intake was set at  $1000\text{ mg per day}$  [57]. Accelerated deterioration of renal function was recorded in a number of reports in patients with renal insufficiency receiving  $1,25(\text{OH})_2\text{D}_3$  therapy [58]. Compared with oral therapy, intravenous administration of  $1,25(\text{OH})_2\text{D}_3$  to renal dialysis patients induces hypercalcemia less frequently, with a smaller increment in the serum calcium concentration and a more effective reduction of PTH levels [59]. Other studies, however, suggest that intermittent oral pulse administration of  $1,25(\text{OH})_2\text{D}_3$  may be effective, though not as effective as intravenous  $1,25(\text{OH})_2\text{D}_3$ , in suppressing PTH in uremic patients with secondary hyperparathyroidism [60–62] (see Chapter 79).

### 2.3 Toxicity due to synthetic vitamin D analogs

In one trial, oral pulse therapy with  $1\alpha$ -hydroxyvitamin  $\text{D}_3$  ( $1\alpha\text{-OHD}_3$ ) resulted in a rapid control of secondary hyperparathyroidism without causing hypercalcemia or hyperphosphatemia [63]. However,  $1\alpha\text{-OHD}_3$  harbors potential calcemic effects similar to  $1,25(\text{OH})_2\text{D}_3$  in the treatment of renal osteodystrophy. Crocker et al. [64] investigated the comparative toxicity of vitamin D,  $1\alpha\text{-OHD}_3$ , and  $1,25(\text{OH})_2\text{D}_3$  in weanling male mice at three different doses over a 4-week period.  $1\alpha\text{-OHD}_3$  appeared to be more toxic in the high-dose group only, with significantly higher serum calcium levels, higher urinary calcium excretion, and severe nephrocalcinosis.  $1\alpha\text{-OHD}_3$  has been described as less potent than  $1,25(\text{OH})_2\text{D}_3$  at low doses but equipotent at doses greater than  $2.0\text{ }\mu\text{g/day}$ . At the higher doses, there is a delayed onset of action and a prolonged half-life, suggesting a potential for cumulative toxicity in renal insufficiency [65,66].

The potential for hypercalcemia, hypercalciuria, and soft-tissue calcifications limits the clinical usefulness of  $1\alpha\text{-OHD}_3$ . Mortensen and colleagues compared the toxicity of both  $1\alpha\text{-OHD}_3$  and  $1,25(\text{OH})_2\text{D}_3$  in rats fed standard or low-calcium diets. High doses of either compound resulted in severe hypercalcemia, with retarded growth, nephrosis, and structural bone changes in the rats fed the standard diet. On the low-calcium diet, however, slight hypercalcemia occurred, but without growth retardation or bone changes. There was minimal effect on the kidney. Calcium restriction again proved effective in protecting the animals against the toxic effects of the vitamin D analogs. Animals fed the low-calcium diet tolerated  $1\alpha\text{-OHD}_3$  at dose levels up to 10 times higher than rats on the standard diets [67]. In human subjects,  $1\alpha\text{-OHD}_3$  can be associated with hypercalcemia at doses above  $1.0\text{ }\mu\text{g/day}$ , but amounts between  $0.5$  and  $1.0\text{ }\mu\text{g/day}$  appear to be safe.

Because of the relatively narrow therapeutic window of vitamin  $\text{D}_3$  1-hydroxylated compounds, a synthetic analog of vitamin  $\text{D}_2$ ,  $1\alpha\text{-OHD}_2$  (doxercalciferol), was developed with the concept that the window of therapeutic efficacy to toxicity would be wider. Doses of doxercalciferol ranging from  $1.0$  to  $5.0\text{ }\mu\text{g/day}$  were administered to 15 female postmenopausal osteopenic subjects. There was no evidence of vitamin D toxicity manifesting as either hypercalciuria or hypercalcemia, whereas significant therapeutic effects on osteoblastic activity were demonstrated [68]. Similar to the  $1\alpha\text{-OHD}_3$ , doxercalciferol requires obligatory hepatic 25-hydroxylation for activation. However, doxercalciferol is able to activate its catabolic pathway via hepatic 24-hydroxylation with a lower potential for toxicity [69].

Because of our emerging greater understanding of the nonclassic target tissue effects of vitamin D in the modulation of hormones and cytokines, and in the regulation of cellular differentiation and proliferation, newer clinical uses have been developed (see Sections X and XI of this book). The clinical applications of these newer properties of vitamin D, however, have also been tempered by the potential for complications, such as hypercalcemia and hypercalciuria. These concerns have prompted the development of additional analogs to better distinguish calcemic from antiproliferative effects [70] discussed in Section X of this book. Depending on the chemical modification of the basic structure of vitamin D, some analogs do demonstrate reduced calcemic activity, but others have been developed that exhibit increased calcemic activity due to enhanced intestinal calcium absorption and bone mineral mobilization. Fluorination of C-24, C-26, or C-27 apparently results in markedly increased calcemic activity resulting from reduced enzymatic

degradation of the side chain. Calcemic potency of  $1,25(\text{OH})_2\text{D}_3$  and its analogs can be also enhanced at least two- to fivefold by epimerization at the C-20 site [71].

The vitamin D analogs in use for secondary hyperparathyroidism in the United States include doxercalciferol and paricalcitol (19-nor-1,25-dihydroxyvitamin  $\text{D}_2$ ). Alfacalcidol, falecalcitriol, and 22-oxacalcitriol are in use outside the United States. Each analog retains suppressive action on PTH and parathyroid gland growth, but has less calcemic and phosphatemic activity than calcitriol. Paricalcitol and doxercalciferol appear to be equally effective in suppressing PTH; however, paricalcitol has been found to be less hypercalcemic [72]. Overall, the effect of vitamin D analogs to control the calcium–phosphate product might reduce vascular calcification and mortality in the renal failure population. However, observational and animal data [73,74] have yet to be confirmed by a randomized control trial [75]. Of additional potential importance may be the decreased likelihood of low bone turnover, or adynamic bone disease, with the use of these agents [76–78]. The mechanism for the differential actions of vitamin D analogs is not completely understood. Oxacalcitriol, for example, has a low affinity for vitamin D–binding protein, so more of the drug circulates in the free form, allowing it to be more rapidly metabolized than calcitriol [79]. This leads to a shorter half-life, which could explain the small and transient stimulation of intestinal calcium absorption. It does not, however, seem to account for the prolonged inhibition of PTH release. The use of analogs in end-stage renal disease is discussed in [Chapter 79](#).

Other vitamin D analogs, such as topical calcipotriol, have proved very effective in the treatment of psoriasis (see [Chapter 104](#)). Because of its low absorption rate and rapid degradation, calcipotriol is believed to have negligible effects on systemic calcium homeostasis when administered topically. However, isolated cases of hypercalcemia and hypercalciuria have been reported [80], even in patients using prescribed doses [81]. Bourke and colleagues noted suppression of serum PTH concentrations in all patients within 2 weeks of treatment with topical calcipotriol. Mean serum and urine calcium levels increased during treatment and fell following withdrawal [82]. The authors concluded that although this particular synthetic analog alters serum and urinary calcium with a dose-dependent effect on systemic calcium homeostasis, it is well tolerated and effective for mild to moderate chronic plaque psoriasis. However, it is potentially hazardous in extensive, unstable, exfoliative disease where increased absorption by inflamed and damaged skin can cause hypercalcemia [81].

### 3. Forms of endogenous Vitamin D toxicity

#### 3.1 Endogenous production of 25-hydroxyvitamin D

Endogenous dysregulation of vitamin D metabolites may be seen in Williams–Beuren syndrome (WBS; OMIM 194050), an idiopathic infantile form of hypercalcemia. WBS is also associated with elfin facies, late psychomotor development, selective mental deficiency, and supravalvular aortic stenosis [83]. Among 232 individuals with WBS aged 0–67 years, the prevalence of hypercalcemia was 17% in infants and 26% in toddlers [84]. The level of hypercalcemia has been reported to range widely from 12 to 19 mg/dL and usually subsides by 4 years of age; however, it may recur during puberty. The etiology of the hypercalcemia in WBS remains unknown. Early reports suggested an exaggerated production of  $25(\text{OH})\text{D}$  with small doses of vitamin D as a possible cause of the hypervitaminosis D [85]. However, recent cases have shown normal  $25(\text{OH})\text{D}$  levels, which may indicate an etiology unrelated to abnormal vitamin D metabolism [86,87].

#### 3.2 Endogenous production of 1,25-dihydroxyvitamin D

##### 3.2.1 Granulomatous diseases

In contrast to the megadosages of exogenous vitamin D that are usually required to produce vitamin D toxicity, patients with granulomatous diseases can develop hypercalcemia rather easily without excessive intake of exogenous vitamin D. They are said to be hypersensitive to vitamin D. The etiology of the vitamin D toxicity in this syndrome is due to poorly regulated extrarenal synthesis of  $1,25(\text{OH})_2\text{D}_3$  by the granulomatous tissue itself. In contrast to the various presentations of vitamin D toxicity described earlier, the responsible metabolite in granulomatous disease is quite different. In the case of vitamin D toxicity due to overdosage of vitamin D or  $25(\text{OH})\text{D}$ ,  $25(\text{OH})\text{D}$  becomes the active metabolite; renal production of  $1,25(\text{OH})_2\text{D}_3$  in this setting is highly regulated and not excessively high due to suppression of PTH by the slightest rise in serum calcium and feedback inhibition of  $1\alpha\text{-OHase}$  by the rising levels of  $1,25(\text{OH})_2\text{D}_3$ . In granulomatous tissue, however,  $1,25(\text{OH})_2\text{D}_3$  formation is not subject to control by any recognized regulators, such as PTH, phosphorus, or calcium. Thus, this syndrome is due to ectopic production of  $1,25(\text{OH})_2\text{D}_3$  by the granulomatous tissue itself. The mechanisms by which hypercalcemia occurs, however, are similar to all other vitamin D toxic states, namely, increased intestinal calcium absorption and enhanced osteoclastic

bone resorption [88,89]. Many studies have led to greater understanding of the pathophysiology and immunological features associated with this syndrome. The role of extrarenal  $1\alpha$ -OHase activity as a source of endogenous  $1,25(\text{OH})_2\text{D}_3$  production in granulomatous disease and other disorders is discussed in much greater detail in [Chapter 9](#).

### 3.2.2 Sarcoidosis

Abnormalities in calcium metabolism have long been noted in patients with sarcoidosis [90]. Sarcoidosis is also the most common granulomatous disease associated with hypercalcemia. Approximately 10%–20% of patients with sarcoidosis may develop hypercalcemia [91,92]. However, severe hypercalcemia is uncommon [93]. Approximately 50% of patients will experience hypercalciuria at some time during the course of the disease, with hypercalciuria invariably present when patients develop hypercalcemia [77]. In the 1950s, studies had already revealed similarities between hypercalcemia of sarcoidosis and the hypercalcemia of vitamin D toxicity, namely, increased intestinal absorption of calcium, hypercalciuria, and therapeutic efficacy of glucocorticoids [94,95]. The major distinguishing feature was in the amount of vitamin D associated with the hypercalcemia and/or hypercalciuria. Seasonal variation of the serum calcium level in sarcoidosis was correlated with availability of sunlight as a source of vitamin D [96]. In the late 1970s, two independent groups showed that the vitamin D–like principle that appeared to be responsible in sarcoidosis was, in fact, the active metabolite of vitamin D,  $1,25(\text{OH})_2\text{D}_3$  [89,97].

Ectopic production of  $1,25(\text{OH})_2\text{D}_3$  was confirmed by demonstrating high circulating concentrations of  $1,25(\text{OH})_2\text{D}_3$  in anephric patients with sarcoidosis on hemodialysis during hypercalcemic episodes [98,99]. This observation showed unequivocally that the kidney, usually the predominant source of  $1,25(\text{OH})_2\text{D}_3$  in nonpregnant individuals, could not be the source of  $1,25(\text{OH})_2\text{D}_3$  in these patients. The serum calcium and  $1,25(\text{OH})_2\text{D}_3$  levels were positively correlated with indices of disease activity [100–102], namely, the extent of granuloma formation and the angiotensin-converting enzyme level. It was subsequently shown that the granulomatous tissue was, in fact, the site of  $1,25(\text{OH})_2\text{D}_3$  production. The  $1\alpha$ -hydroxylase enzyme responsible for formation of  $1,25(\text{OH})_2\text{D}_3$  was present in lymph node homogenates [103]. Moreover, pulmonary alveolar macrophages [104] could be shown to catalyze the formation of an  $^3\text{H}$ -labeled  $25(\text{OH})\text{D}_3$  metabolite. This metabolite was definitively identified as  $1,25(\text{OH})_2\text{D}_3$  by high-performance liquid chromatography (HPLC), by the chick intestinal receptor assay for  $1,25(\text{OH})_2\text{D}_3$ , by UV spectroscopy, and by mass

spectrometry [105]. The production of mRNA for  $1\alpha$ -OHase (CYP27B1) is markedly increased in alveolar macrophages isolated from hypercalcemic patients with sarcoid [106]. Importantly, control of the macrophage  $1\alpha$ -OHase enzyme differs from that of the renal  $1\alpha$ -OHase. The renal  $1\alpha$ -OHase is regulated at the level of transcription by calcitropic hormones, especially PTH, and is exquisitely autoregulated by  $1,25(\text{OH})_2\text{D}_3$  itself [107]. In contrast, macrophage  $1\alpha$ -OHase mRNA expression is potently stimulated by inflammatory agents, such as  $\gamma$ -interferon [108], and shows no feedback control in response to  $1,25(\text{OH})_2\text{D}_3$  [109]. Communication between signaling pathways of  $\gamma$ -interferon and the vitamin D receptor has been reported [110]. These mechanisms account for the uncontrolled synthesis of  $1,25(\text{OH})_2\text{D}_3$  and the characteristic finding of increased sensitivity to vitamin D in these patients [111,112]. Another property of the macrophage  $1\alpha$ -OHase enzyme is that it is inhibited in a dose-dependent fashion by dexamethasone and chloroquine that do not influence the renal  $1\alpha$ -OHase enzyme that catalyzes synthesis of  $1,25(\text{OH})_2\text{D}_3$  [113]. These in vitro observations have direct clinical relevance and suggest possible treatments of hypercalcemia due to sarcoidosis. There are several mechanisms by which calcium metabolism is disturbed in sarcoidosis [114]. First,  $1,25(\text{OH})_2\text{D}_3$  causes hypercalcemia, in part, by stimulating intestinal calcium absorption. A low-calcium diet [115,116], alone or in association with cellulose phosphate [117], was found to normalize the calcium level in some patients with sarcoidosis. Second,  $1,25(\text{OH})_2\text{D}_3$  directly stimulates osteoclastic-mediated bone resorption; skeletal granulomas are not required for this effect [118–120]. The increased flux of calcium into the extracellular space by these gastrointestinal and skeletal mechanisms, aided by suppression of PTH [97–99], leads to hypercalciuria. Chronic hypercalciuria favors nephrocalcinosis and renal stone formation [121]. When the kidneys are unable to excrete the calcium presented to them, because of either declining renal function, enhanced bone resorption, a sudden influx of dietary calcium, dehydration, or any combination of these events, hypercalcemia ensues [122]. Granulomatous production of PTHrP may also play a role in abnormal calcium metabolism, where TNF $\alpha$  and interleukin-6, produced by macrophages, increase PTHrP gene expression. For example, a 67-year-old man with sarcoidosis developed hypercalcemia with concurrently elevated PTHrP. Immunohistochemistry staining demonstrated PTHrP expression in bone marrow granulomas. Treatment with glucocorticoids normalized hypercalcemia and the PTHrP level [123]. In another series, PTHrP was present in 85% of biopsies of granulomatous tissue from patients with sarcoidosis [124].

### 3.2.3 Tuberculosis

Longitudinal studies from the United States [125] and India [126] suggested that 16%–28% of patients with tuberculosis develop hypercalcemia. However, in these early studies, vitamin D supplements were employed, increasing the risk and severity of hypercalcemia. A similar study from Greece [127] reported a figure as high as 48% when serum calcium was corrected to a normal albumin level. Other studies from the United Kingdom [128], Belgium [129], Hong Kong [130], and Malaysia [131] have shown a much lower prevalence of hypercalcemia, in the range of 0%–2.3%. It is likely that hypercalcemia is not as common in tuberculosis as was previously thought [132]. This discrepancy might be attributable to regional differences in calcium and vitamin D intake, which can unmask hypercalcemia [133], along with increased sun exposure.

Reports of high circulating levels of  $1,25(\text{OH})_2\text{D}_3$  in three anephric patients with tuberculosis support an extrarenal source of the active vitamin D metabolite [134,135]. Positive correlation of the albumin-adjusted calcium level with the radiographic extent of the disease has been shown [130]. Hypercalcemia in tuberculosis may occur weeks to months after starting antituberculosis chemotherapy [125,126]. Thus, the hypercalcemia is not related to the presence of viable acid-fast bacilli, but rather to the granulomatous process and associated reactions. As with sarcoidosis, hypercalcemia in tuberculosis can be controlled by administration of glucocorticoids [136].

In patients with tuberculous pleuritis, the mean free  $1,25(\text{OH})_2\text{D}_3$  concentration in pleural fluid was selectively concentrated by 5.3-fold over that in serum [137]. Positive correlation between the concentrations of substrate  $25(\text{OH})\text{D}_3$  and product  $1,25(\text{OH})_2\text{D}_3$  in pleural fluid supported the idea that  $1,25(\text{OH})_2\text{D}_3$  was produced locally by activated inflammatory cells in or adjacent to the pleural space. The pleural fluid was found to have high concentrations of  $\gamma$ -interferon, a cytokine known to stimulate activated macrophages in vitro to synthesize  $1,25(\text{OH})_2\text{D}_3$  [138]. Cells obtained from bronchoalveolar lavage in patients with tuberculosis were also found to synthesize  $1,25(\text{OH})_2\text{D}_3$  in vitro. An important source of the active vitamin D metabolite appears to be the CD8+ T lymphocytes at the granulomatous sites [139]. If one considers etiologically about the production of  $1,25(\text{OH})_2\text{D}_3$  under these circumstances, the immunomodulatory functions of  $1,25(\text{OH})_2\text{D}_3$  acting as a beneficial local paracrine factor could be pertinent. In fact, increased levels of  $1,25(\text{OH})_2\text{D}_3$  have been found to result in the production of cathelicidin, a peptide with antimicrobial properties against *Mycobacterium tuberculosis*, by macrophages [140] (see Chapter 94 and Chapter 98). Viewed in this

context, hypercalcemia occurs when  $1,25(\text{OH})_2\text{D}_3$  is produced in such quantities that it gains entry into the circulation. Hypercalcemia in tuberculosis is usually mild and asymptomatic. Besides glucocorticoids, ketoconazole administration has been associated with a rapid decline in  $1,25(\text{OH})_2\text{D}_3$  and normalization of serum calcium levels, through inhibition of  $1\alpha$ -OHase [141]. Long-term antituberculosis therapy with isoniazid and rifampin can also be effective in treating the hypercalcemia by controlling the disease.

### 3.2.4 Foreign material

Introduction of foreign material into the human body can lead to a granulomatous inflammatory reaction resulting in hypercalcemia due to excessive  $1,25(\text{OH})_2\text{D}_3$  production. A growing number of substances have been reported to induce this reaction including talc-induced granulomatous pneumoconiosis pneumonia [142], granulomatous reaction to silicone injections [143–146], polymethylmethacrylate injections [147–149], and cosmetic injections of paraffin oil [150] and mineral oil [151]. Particle disease, resulting from an inflammatory macrophage reaction to shredded particulates from a failed prosthetic joint, has also been associated with hypercalcemia and elevated  $1,25(\text{OH})_2\text{D}_3$ , which was responsive to treatment with glucocorticoids [152].

### 3.2.5 Other granulomatous diseases

Hypercalcemia associated with other granulomatous disorders is relatively rare and the subject of case reports, but it has been described in infectious etiologies including coccidioidomycosis [153], histoplasmosis [154], candidiasis [155], cat-scratch disease [156], *Pneumocystis jirovecii* pneumonia [157–161], paracoccidioidomycosis [162], and *Mycobacterium avium* complex [163]. Immune reconstitution inflammatory syndrome led to hypercalcemia with elevated  $1,25(\text{OH})_2\text{D}_3$  in three patients with a documented history of HIV who also had mycobacterium tuberculosis [164,165] or *Mycobacterium avium* complex [166].

Hypercalcemia was also reported as a systemic reaction to Calmette-Guérin bacillus (BCG) therapy for bladder cancer complicated by disseminated granulomatosis [167]. Noninfectious etiologies, aside from sarcoidosis, have been reported with granulomatosis with polyangiitis [168–170], Langerhans' cell granulomatosis [171], Crohn's disease [172–174], infantile fat necrosis [175], giant cell polymyositis [176], gastrointestinal stromal tumors [177–179], and in some patients on chronic hemodialysis with hepatic granulomatosis of unknown etiology [180].

Malakoplakia, due to nongranulomatous macrophage infiltration, has also been associated with

hypercalcemia due to 1- $\alpha$ -hydroxylase activity in the malakoplakia cell [181]. Massive lymphadenopathy resulting from proliferation of histiocytes in lymph nodes, an entity known as Rosai-Dorfman disease, led to hypercalcemia and increased serum 1,25(OH) $_2$ D $_3$  levels in one case [182]. Acute granulomatous pneumonitis, a rare complication of methotrexate therapy, can also lead to hypercalcemia with elevated 1,25(OH) $_2$ D $_3$  [183].

Several rare dermatologic conditions including necrobiotic xanthogranuloma, a chronic granulomatous disease primarily involving the skin [184], palisaded neutrophilic and granulomatous dermatitis, a benign inflammatory dermatosis [185], and granulomatous slack skin disease, a rare T cell lymphoproliferative disorder, have all been associated with hypercalcemia and elevated 1,25(OH) $_2$ D $_3$  in Ref. [186]. Additionally, idiopathic hypereosinophilic syndrome has also been shown to cause hypercalcemia with elevated 1,25(OH) $_2$ D $_3$  [187].

The mechanism of increased production of the active vitamin D metabolite is believed to be shared by all of these granulomatous disorders. Autonomous excess production of calcitriol in the absence of granulomatous disease has also been reported in patients with elevated angiotensin converting enzyme levels [188], presumably with increased calcitriol production by macrophages. A possible role for 1,25(OH) $_2$ D $_3$  in these granulomatous disorders as noted before includes immunomodulatory features. Interesting, an experimental analog of cAMP (8-Cl-cAMP) given to patients with advanced solid malignancies was shown to cause hypercalcemia associated with elevated levels of 1,25(OH) $_2$ D $_3$  not clearly associated with a granulomatous reaction [189].

### 3.2.6 Lymphoma

Hypercalcemia has been reported to occur in up to 5% [190] and 15% [191] of patients with Hodgkin's disease and non-Hodgkin's lymphoma (NHL), respectively. Up to 80% of patients with human T cell leukemia virus type 1 (HTLV-1)–associated adult T cell lymphoma/leukemia (ATLL) may develop hypercalcemia [192]. As is the case with other malignancies, hypercalcemia is a poor prognostic feature in lymphoma [193,194], adding substantially to morbidity and mortality. The humoral mediators of hypercalcemia in lymphoma are multiple and heterogenous. However, evidence has shown 1,25(OH) $_2$ D $_3$  to be an important factor in many cases.

The development of hypercalcemia in Hodgkin's disease is most consistently associated with 1,25(OH) $_2$ D $_3$ . Since the first report of hypercalcemia complicating Hodgkin's disease in 1956 [195], more than 60 cases have been described. In a retrospective review of the literature [196], 84% of patients had a peak serum calcium above 12 mg/dL, 74% of the patients had Ann

Arbor stage III or IV disease, and 68% were symptomatic with night sweats, fever, and weight loss. Only 3 of 23 patients had radiological evidence of lytic bone lesions. In 17 hypercalcemic patients, all but one patient had an elevated 1,25(OH) $_2$ D $_3$  level. There is no evidence to implicate parathyroid hormone–related peptide (PTHrP) as a mediator of hypercalcemia in Hodgkin's disease. Two patients with Hodgkin's disease [197,198] were reported to have intermittent hypercalcemia during two consecutive summers or on vitamin D challenge. There was a close association between hypercalcemia and the high 1,25(OH) $_2$ D $_3$  level, with the serum 25(OH)D $_3$  being maintained within the normal range. These observations support the idea that the mechanism of the hypercalcemia in Hodgkin's disease is similar to that of the granulomatous diseases, namely, production by the lymphomatous tissue of 1,25(OH) $_2$ D $_3$ .

A number of cases of 1,25(OH) $_2$ D $_3$ -induced hypercalcemia in non-Hodgkin's lymphoma have been described [196]. Most patients had bulky or advanced-stage disease, but no clinically or radiographically evident bone lesions. In one case, the 1,25(OH) $_2$ D $_3$ -mediated hypercalcemia was associated with transformation from a chronic lymphocytic leukemia to an aggressive high-grade non-Hodgkin's lymphoma [199]. Seymour et al. [200] prospectively studied patients with non-Hodgkin's lymphoma and found that 12 of 22 patients (55%) with hypercalcemia had elevated serum calcitriol levels compared with a group of patients with hypercalcemia due to multiple myeloma. Additionally, 71% of patients with normal serum calcium had hypercalciuria, and 18% had elevated serum 1,25(OH) $_2$ D $_3$  levels. Data supporting extrarenal synthesis of 1,25(OH) $_2$ D $_3$  include the presence of severe renal failure in a number of instances [201,202]; the demonstration of in vitro conversion of 25(OH)D $_3$  to 1,25(OH) $_2$ D $_3$  by excised lymph node homogenates [203]; the prompt decline of 1,25(OH) $_2$ D $_3$  levels to normal after excision of an isolated splenic lymphoma [204]; a primary ovarian lymphoma [205]; and sensitivity to glucocorticoid suppression [202]. 5 of 10 patients with either HIV or non-HIV-associated non-Hodgkin's lymphoma and hypercalcemia had frankly elevated serum 1,25(OH) $_2$ D $_3$  concentrations [206]. Other malignant lymphoproliferative diseases associated with 1,25(OH) $_2$ D $_3$ -mediated hypercalcemia include lymphomatoid granulomatosis [207], dysgerminoma [208], and an inflammatory myofibroblastic tumor [209].

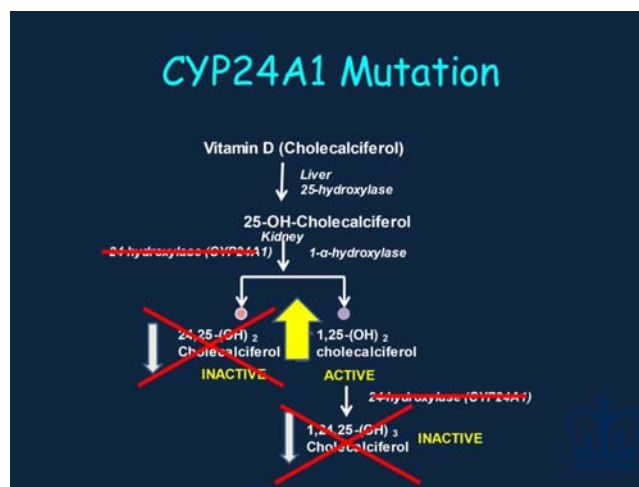

The precise cell type responsible for the extrarenal synthesis of 1,25(OH) $_2$ D $_3$  in lymphoma remains to be established. There are two possibilities. One is the tumor-infiltrating reactive macrophage, recognized by a "starry-sky" appearance [210] in intermediate and high-grade lymphomas, in which hypercalcemia is also

Although HTLV-1-transformed lymphocytes were shown *in vitro* to possess the capacity to convert 25(OH)D<sub>3</sub> to 1,25(OH)<sub>2</sub>D<sub>3</sub> [217], most studies have shown reduced 1,25(OH)<sub>2</sub>D<sub>3</sub> levels in hypercalcemia associated with HTLV-1-related adult T cell leukemia/lymphoma [218,219]. PTHrP is most strongly implicated as the major mediator in this syndrome [220]. PTHrP messenger RNA has been demonstrated in HTLV-1-infected T cells [221] and tumor cells from adult T cell lymphoma/leukemia (ATLL) patients with hypercalcemia [222]. Nevertheless, there are two well-documented instances of elevated 1,25(OH)<sub>2</sub>D<sub>3</sub> levels in ATLL [192,201]. In the first case, a PTHrP level was not available. In the second case, concomitant elevation of 1,25(OH)<sub>2</sub>D<sub>3</sub> and PTHrP was shown, suggesting the possibility of increased renal 1 $\alpha$ -OHase activity secondary to PTHrP. Alternatively, the tissue could be the site of both PTHrP and 1,25(OH)<sub>2</sub>D<sub>3</sub> formation. Other malignancies associated with 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated hypercalcemia include seminoma [223], leiomyoblastoma [224], and squamous cell bronchogenic carcinoma [225]. Most patients with hypercalcemia due to classic squamous cell carcinoma have elevated PTHrP levels and either suppressed or normal 1,25(OH)<sub>2</sub>D<sub>3</sub> levels [226].

The 24-hydroxylase (24-OHase) enzyme is responsible for the metabolism of active 1,25(OH)<sub>2</sub>D<sub>3</sub> to the inactive metabolite 1,24,25-trihydroxyvitamin D (1,24,25(OH)<sub>2</sub>D<sub>3</sub>). Loss of 24-OHase, the enzyme produced by the *CYP24A1* gene, prevents inactivation of vitamin D metabolites at several steps (Fig. 81.1). Inactivating mutations in *CYP24A1* gene can result in idiopathic infantile hypercalcemia (OMIM 143880), characterized by hypercalcemia, hypotonia, nephrocalcinosis and failure to thrive in infancy. Schlingmann et al. reported six patients from four families with idiopathic infantile hypercalcemia and found loss-of-function mutations in *CYP24A1* that appeared to be associated with disease development [227]. The disease has also been diagnosed in adults. Tebben et al. reported a family of patients with hypercalcemia, hypercalciuria, nephrolithiasis, and elevated 1,25-dihydroxyvitamin D levels [228]. Genetic testing revealed *CYP24A1* mutations in three generations of this family. A report from Jacobs et al. described a man with a long-standing history of hypercalcemia and nephrolithiasis diagnosed in his early 20s who was eventually diagnosed with an inactivating mutation of *CYP24A1* at age 73 years after the advent of genetic testing [229]. There have been multiple subsequent case reports in adults diagnosed with this disorder [228,230–236].

Vitamin D toxicity may occur in patients due to any one of the three forms of vitamin D, namely, the

**FIGURE 81.1** The effects of inactivating mutations in the CYP24A1 gene with resultant loss of 24-hydroxylase activity on the catabolism of vitamin D metabolites. *Figure adapted with permission from Marcella Walker, MD.*

vitamin D parent compound, 25(OH)D or 1,25(OH)<sub>2</sub>D<sub>3</sub>. Multiple factors may influence susceptibility to vitamin D toxicity and include the concentration of the vitamin D metabolite itself, vitamin D receptor (VDR) number, activity of 1 $\alpha$ -OHase, the metabolic degradation pathway, and the capacity of the DBP. Vitamin D<sub>2</sub> or D<sub>3</sub> toxicity is more difficult to manage than toxicity due to its metabolites 25(OH)D or 1,25(OH)<sub>2</sub>D<sub>3</sub>. In part, this is due to the extensive lipid solubility of the parent compound in liver, muscle, and fat tissues and corresponding large storage capacity. As a result, the half-life of vitamin D ranges from 20 days to months. In contrast, the biological half-life of the less lipophilic compound 25(OH)D is shorter, approximately 15 days [237]. The biological half-life of the least lipophilic compound 1,25(OH)<sub>2</sub>D<sub>3</sub> is much shorter, approximately 15 h [238]. In general, duration of toxicity is related to the half-life of the vitamin D compound. Thus, the hypercalcemia of parent vitamin D overdose can theoretically last for as long as 18 months, long after dosing is discontinued, because of its slow release from fat deposits. Overdosage of 25(OH)D can persist for weeks also, but excessive 1,25(OH)<sub>2</sub>D<sub>3</sub> toxicity is more rapidly reversed because 1,25(OH)<sub>2</sub>D<sub>3</sub> is not stored in appreciable amounts in the body [101].

The toxicity of either parent vitamin D or 25(OH)D is due to 25(OH)D. In an investigation examining the concentrations of vitamin D<sub>3</sub> and its metabolites in the rat as influenced by various intakes of vitamin D<sub>3</sub> or 25(OH)D, Shepard and DeLuca found that intakes of vitamin D<sub>3</sub>, ranging from 1 to 10,000 IU daily (0.65–6500 nmol/day), resulted in excessive concentrations of vitamin D<sub>3</sub> and 25(OH)D<sub>3</sub> but not in 1,25(OH)<sub>2</sub>D<sub>3</sub> [239]. Similarly, increased dosages of 25(OH)D<sub>3</sub> ranging from 0.46 to 4600 nmol/day resulted in excessive amounts of 25(OH)D<sub>3</sub>, but not of vitamin D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub>. Unlike 1,25(OH)<sub>2</sub>D<sub>3</sub> whose production is tightly regulated in the kidney, the production of 25(OH)D in the liver is not tightly controlled. The high capacity for 25-hydroxylation of vitamin D in the liver as well as limited regulation at this site allows for massive amounts of 25(OH)D to be generated from large amounts of vitamin D. Thus, excessive concentrations of 25(OH)D are typically measured in vitamin D toxicity. Hypercalcemia appears to result only when 25(OH)D concentrations are consistently above 150 or 200 ng/mL (375 nmol/L) in normal individuals [3,240]. In patients with a secondary condition that can contribute to the development of hypercalcemia, toxicity can develop at lower 25(OH)D concentrations [17]. As would be expected, PTH levels are suppressed in this form of hypercalcemia. In the setting of toxicity due to overadministration of 1,25(OH)<sub>2</sub>D<sub>3</sub>, the active metabolite itself is responsible for the hypercalcemia [241].

## 4.2 Role of vitamin D receptor in vitamin D toxicity

Various investigations have helped to shed light on the interrelationship among vitamin D metabolites, the VDR, and PTH in vitamin D toxicity. The biologically active form of vitamin D, 1,25(OH)<sub>2</sub>D<sub>3</sub>, as is typical of other steroid hormones, binds to a specific intracellular receptor protein (VDR) within its target tissues. The hormone–VDR complex then triggers subsequent transcriptional events by binding to DNA elements.

Regulation of cellular VDR numbers is believed to be an important mechanism by which cellular responsiveness to 1,25(OH)<sub>2</sub>D<sub>3</sub> is modulated, because the biological activity of 1,25(OH)<sub>2</sub>D<sub>3</sub> is proportional both to tissue VDR number and concentration of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Increased VDR concentrations imply enhanced tissue responsiveness to 1,25(OH)<sub>2</sub>D<sub>3</sub>, whereas decreased receptor numbers indicate reduced tissue responsiveness. Several investigations have suggested that exogenous 1,25(OH)<sub>2</sub>D<sub>3</sub> can lead to homologous upregulation of VDR in vitro and in vivo, in contrast to endogenous production of 1,25(OH)<sub>2</sub>D<sub>3</sub>. In vitro and in vivo administration of 1,25(OH)<sub>2</sub>D<sub>3</sub> to rats has been shown to increase VDR content. In vitro exposure of human skin fibroblasts and osteosarcoma cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> has been shown to result in a three- to fivefold increase in VDR number [242]. Similarly, in vivo studies have shown increased VDR with exogenous administration of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Costa and Feldman administered 1500 pmol/kg of 1,25(OH)<sub>2</sub>D<sub>3</sub> daily to rats and found a 30% increase in intestinal VDR and a threefold increase in renal VDR concentration [243]. Reinhart et al. infused rats with 250 pmol/kg of 1,25(OH)<sub>2</sub>D<sub>3</sub> daily for 6 days and noted a 22% increase in VDR levels in the intestine and a 37% increase in bone [244]. Goff and colleagues infused 36 ng of 1,25(OH)<sub>2</sub>D<sub>3</sub> to rats over 7 days and found a 1.5-fold increase in duodenal VDR content and a threefold increase in renal VDR content [245].

Goff et al. [245] also demonstrated that endogenously produced 1,25(OH)<sub>2</sub>D<sub>3</sub> has a different effect than exogenous administration of 1,25(OH)<sub>2</sub>D<sub>3</sub> on tissue VDR content. Rats fed a calcium-restricted diet resulting in “nutritional” hyperparathyroidism achieved a similar increase in endogenous 1,25(OH)<sub>2</sub>D<sub>3</sub> concentration as rats administered exogenous 1,25(OH)<sub>2</sub>D<sub>3</sub>. However, calcium-restricted rats failed to upregulate VDR content in the duodenum or kidney, presumably a consequence of the negative control of VDR by PTH [246]. This point has at least conceptual relevance in the case of vitamin D toxicity. Rather than downregulation occurring during hypervitaminosis D, which is a more typical regulatory and protective event to limit tissue responsiveness, exposure of cells to exogenous 1,25(OH)<sub>2</sub>D<sub>3</sub> results in enhanced responsiveness by virtue of upregulation.

Such a mechanism would be of particular clinical relevance if the toxicity were due to overexposure of  $1,25(\text{OH})_2\text{D}_3$ . Moreover, in this setting, the associated suppression of PTH would prevent the regulatory mechanism from being operative.

Evidence suggests that in parent vitamin D toxicity, target tissues are responding to high concentrations of  $25(\text{OH})\text{D}$ , not  $1,25(\text{OH})_2\text{D}_3$ . Concentrations of  $1,25(\text{OH})_2\text{D}_3$  are typically only slightly increased, if at all. The hypercalcemia is due to the effects of pharmacologically high levels of  $25(\text{OH})\text{D}$ , even though  $25(\text{OH})\text{D}$  has a much lower binding affinity for the VDR than  $1,25(\text{OH})_2\text{D}_3$ . At high concentrations,  $25(\text{OH})\text{D}$  can compete for binding at VDR sites and thereby produce biological effects similar to those of  $1,25(\text{OH})_2\text{D}_3$  on intestine and bone [247]. Beckman and colleagues [248] suggested, furthermore, that hypervitaminosis D, like excessive exogenous  $1,25(\text{OH})_2\text{D}_3$ , is associated with homologous upregulation of intestinal VDR. Their investigation demonstrated that supraphysiological amounts of vitamin  $\text{D}_2$  or vitamin  $\text{D}_3$  administered to rats at doses of 25,000 IU daily for 6 days resulted in increasing plasma  $25(\text{OH})\text{D}$  concentrations with significant upregulation of intestinal VDR concentration and hypercalcemia. Plasma  $1,25(\text{OH})_2\text{D}_3$  levels were not altered substantially.

A comparison between hypervitaminosis  $\text{D}_3$  and  $\text{D}_2$  was also made [248]. No differences in  $25(\text{OH})\text{D}$  and plasma calcium concentrations were noted between either of the preparations. Concentrations of  $25(\text{OH})\text{D}$  in each case were markedly higher than the control group. The concentration of  $1,25(\text{OH})_2\text{D}_3$  was observed to be only slightly greater in the vitamin  $\text{D}_3$ -treated group than the vitamin  $\text{D}_2$ -treated group. Because the  $25(\text{OH})\text{D}$  concentrations were elevated 20- to 25-fold, whereas  $1,25(\text{OH})_2\text{D}_3$  showed only minimal increases, the biochemical and clinical changes associated with parent vitamin D toxicity were attributed to  $25(\text{OH})\text{D}$ . The data provided further support for the importance of  $25(\text{OH})\text{D}$  as the major toxic metabolite in vitamin D-associated hypercalcemia, as well as for the importance of increased intestinal VDR in the pathophysiological process that leads to enhanced effects of this metabolite.

### 4.3 Control of renal $1\alpha$ -OHase in vitamin D toxicity

Some investigators have suggested that toxic effects of excessive concentrations of  $25(\text{OH})\text{D}$  may result from PTH suppression and downregulation of  $1\alpha$ -OHase with increased concentrations of  $25(\text{OH})\text{D}$ . PTH and  $1,25(\text{OH})_2\text{D}_3$  have known reciprocal actions on  $1\alpha$ -OHase and  $24$ -OHase activities. PTH stimulates

$1\alpha$ -OHase activity and downregulates  $24$ -OHase activity;  $1,25(\text{OH})_2\text{D}_3$ , on the other hand, downregulates  $1\alpha$ -OHase activity and stimulates  $24$ -OHase activity.

Beckman and colleagues [249] studied the effects of an excess of vitamin  $\text{D}_3$  and dietary calcium restriction on tissue  $1\alpha$ -OHase and  $24$ -OHase activity in rats. Four groups of rats with different dietary calcium and vitamin  $\text{D}_3$  concentrations were studied (normal calcium, NC; low calcium, LC; and the excess vitamin D groups with normal or low calcium, NCT and LCT). The data showed that in the setting of a calcium-restricted diet, a nutritional hyperparathyroidism ensued. Under conditions of excess vitamin  $\text{D}_3$  at doses of 75,000 IU per week and on a calcium-restricted diet, elevations in PTH facilitated the elimination of  $25(\text{OH})\text{D}_3$  through its metabolism to  $1,25(\text{OH})_2\text{D}_3$  and/or degradation to  $24,25(\text{OH})_2\text{D}_3$ . The elevation in PTH was accompanied by increased activation of renal  $1\alpha$ -OHase activity, lower concentrations of  $25(\text{OH})\text{D}_3$ , increased activation of intestinal  $24$ -OHase activity, and lower renal VDR content compared with the normal calcium group. In contrast, the normal calcium diet in the vitamin  $\text{D}_3$  excess group contributed to the toxicity by virtue of suppressed PTH concentrations resulting in downregulation of renal  $1\alpha$ -OHase and decreased  $24$ -OHase activity, and, thus, higher  $25(\text{OH})\text{D}_3$  concentrations. On the other hand, dietary calcium restriction in the setting of vitamin  $\text{D}_3$  excess seemed to be protective, providing less biological stimulation due to higher PTH concentrations with reduced VDR, increased activation of both  $1\alpha$ -OHase and  $24$ -OHase activities, greater reductions in  $25(\text{OH})\text{D}_3$  concentrations, and lower concentrations of total calcium resulting in a less toxic state. So the low-calcium diet protects, not only by contributing to less hypercalcemia, but also by facilitating metabolic pathways of vitamin D inactivation.

### 4.4 Inhibition of the catabolic pathway of $24$ -OHase

Inhibition of the enzymes that degrade the vitamin D metabolites has a role in the pathogenesis of hypervitaminosis D.  $1,25(\text{OH})_2\text{D}_3$  is a known regulator of its own catabolism and an inhibitor of its synthesis. In the kidney, intestine, and other targets,  $1,25(\text{OH})_2\text{D}_3$  induces the enzyme  $24$ -OHase. This enzyme initiates a catabolic cascade that ultimately causes side chain oxidation, cleavage, and metabolic elimination of both  $1,25(\text{OH})_2\text{D}_3$  and  $25(\text{OH})\text{D}$ . It accounts for 35%–40% of the catabolism of  $1,25(\text{OH})_2\text{D}_3$  [250]. The remainder of the metabolic degradation is due to other side chain oxidations and biliary clearance. Reinhart and Horst [251] initially proposed that blunting of the catabolic pathway of  $1,25(\text{OH})_2\text{D}_3$  with high concentrations of

24,25(OH)<sub>2</sub>D<sub>3</sub> in rat cells would competitively inhibit further inactivation of 1,25(OH)<sub>2</sub>D<sub>3</sub>, resulting in an accumulation of 1,25(OH)<sub>2</sub>D<sub>3</sub> and toxicity.

Clinical investigations of the downregulation of rat intestinal 24-OHase and its inhibition by calcitonin helped to elucidate a role of this hormone in potentiating the toxicity of vitamin D. 24-Hydroxylation is important in the inactivation of both 1,25(OH)<sub>2</sub>D<sub>3</sub> and 25(OH)D<sub>3</sub> and, in the kidney, is largely regulated inversely by 1 $\alpha$ -hydroxylation [252]. In a study examining the effects of dietary calcium and vitamin D status on the regulation of intestinal 24-OHase enzyme and mRNA expression, rats were fed normal or low-calcium diets with variable amounts of vitamin D [253]. Half of the rats on the normal and low-calcium diets were administered pharmacological doses of vitamin D<sub>3</sub> (25,000 IU three times weekly). Excess vitamin D<sub>3</sub> resulted in significant elevations in plasma 25(OH)D<sub>3</sub> in both calcium groups, with a much larger increase noted in the normal calcium group. Hypercalcemia was most severe in the normal calcium and vitamin D<sub>3</sub> excess group, whereas rats in the low calcium and vitamin D<sub>3</sub> excess group had plasma calcium levels similar to the normal calcium group not treated with vitamin D. Among the rats treated with excess vitamin D<sub>3</sub>, because the normal calcium group was accompanied by an increased calcitonin concentration compared with the low calcium group, the authors suggested that the increased calcitonin in the normal calcium group may have suppressed 24-OHase activity, with resultant higher 25(OH)D<sub>3</sub> and calcium concentrations. This concept was further supported when rats, subjected to thyroparathyroidectomy, which eliminated endogenous calcitonin, were found to have higher concentrations of 24-OHase activity than the normal calcium and vitamin D<sub>3</sub> excess group. Through inhibition of intestinal 24-OHase activity, calcitonin could be associated with reduced turnover and catabolism of 25(OH)D<sub>3</sub>, thereby potentiating its toxicity. Thus, increased expression of 24-OHase activity in cases of pharmacological amounts of 25(OH)D<sub>3</sub> may be an important mechanism to counteract vitamin D toxicity. A key role for 24-OHase in preventing the development of vitamin D toxicosis was found in a relevant animal study. Growing dogs given 135-fold vitamin D<sub>3</sub> supplementation actually had a decrease in plasma 1,25(OH)<sub>2</sub>D<sub>3</sub> levels by 40% as compared with controls, despite an increase in 1,25(OH)<sub>2</sub>D<sub>3</sub> production. This was attributed to an upgraded catabolism of 1,25(OH)<sub>2</sub>D<sub>3</sub> by 24-OHase, as evidenced by increased gene expression of renal and intestinal 24-OHase, thus providing an efficient hormonal counteraction [254]. Also relevant, St-Arnaud et al. [255] and Masuda et al. [256] showed that a targeted inactivating mutation of the 24-OHase gene in mice resulted in impaired catabolism of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Absence of the 24-OHase gene

during development also resulted in abnormal bone mineralization, with rescue of the phenotype by subsequent inactivation of the VDR. These experiments support a critical role of 24-OHase in preserving vitamin D homeostasis.

Furthermore, and as noted earlier, mutations in the *CYP24A1* gene encoding the 24-OHase enzyme in humans have been shown to be associated with idiopathic infantile hypercalcemia and in adults with hypercalcemia, hypercalciuria, nephrolithiasis, and elevated 1,25-dihydroxyvitamin D levels (see section “Decreased Clearance of 1,25-Dihydroxyvitamin D” under “Forms of Endogenous Vitamin D Toxicity”).

#### 4.5 Vitamin D-binding protein and the level of free metabolite in vitamin D toxicity

DBP is a specific transport protein that binds large quantities of the circulating vitamin D metabolites. Similar to the situation for other steroid hormones, fat-soluble compounds, and thyroid hormones, only a small fraction of the vitamin D metabolites circulate free in plasma. The binding affinity of the protein for the vitamin D metabolites is moderate, and the capacity is great (only 5% of binding sites on DBP are normally occupied). In addition, the various metabolites have different binding affinities for the protein, in the following sequence: 25(OH)D > 24,25(OH)<sub>2</sub>D > 1,25(OH)<sub>2</sub>D<sub>3</sub> [257]. Of note is the fact that the potent metabolite 1,25(OH)<sub>2</sub>D<sub>3</sub> has the least affinity for DBP, but the highest affinity for the intracellular VDR that triggers subsequent transcriptional events. Therefore, freeing bound 1,25(OH)<sub>2</sub>D<sub>3</sub> metabolite from DBP could promote its entry into various tissues and promote biological activity [258]. In states of vitamin D toxicity, the presence of elevated free 1,25(OH)<sub>2</sub>D<sub>3</sub> levels despite normal total 1,25(OH)<sub>2</sub>D<sub>3</sub> levels suggests that 1,25(OH)<sub>2</sub>D<sub>3</sub> is displaced from DBP by 25(OH)D, resulting in a rise of serum free calcitriol [259].

Evidence indicates that the biologically active form of the vitamin D steroid hormone is the free hormone that is accessible to cells [260]. Because of technical difficulties in measuring the free hormone, the determination of vitamin D status involves a measurement combining free vitamin D and DBP concentrations. In normal individuals, 85% of the total 1,25(OH)<sub>2</sub>D<sub>3</sub> is bound to DBP, 15% is bound to albumin, and 0.4% is free [261]. However, under conditions of altered or reduced albumin and DBP concentrations, as in liver or kidney disease, the free hormone may provide different information compared with the total measured concentration of vitamin D. Theoretically, total hormone concentration in such settings may erroneously suggest

deficiency of vitamin D with needless institution of replacement therapy. Bikle and colleagues noted that subjects with liver disease have reduced DBP concentrations with low total  $1,25(\text{OH})_2\text{D}_3$  and  $25(\text{OH})\text{D}$  levels, whereas free forms are normal [262,263].

Similarly, in certain forms of renal disease, the concentrations of DBP and vitamin D metabolites are reduced; thus, measurements of total hormone may provide an inaccurate reflection of vitamin D status. Koenig et al. [264] investigated free and total  $1,25(\text{OH})_2\text{D}_3$  concentrations in subjects with renal disease. Patients with nephrotic syndrome, with a range of degrees of renal failure including those on hemodialysis and peritoneal dialysis, were examined. The serum concentrations of total and free  $1,25(\text{OH})_2\text{D}_3$  correlated well with one another in patients with renal failure and those on hemodialysis. The concentrations of DBP and  $25(\text{OH})\text{D}$ , thus, were unaffected by renal function. The concentrations of total  $1,25(\text{OH})_2\text{D}_3$  accurately reflected free  $1,25(\text{OH})_2\text{D}_3$  in patients with varying degrees of renal failure when DBP levels remained normal. However, this did not hold true for the subjects with nephrotic syndrome or those on chronic peritoneal dialysis, who have losses of DBP and bound vitamin D metabolites into the urine or peritoneal fluid, respectively, with a rise in the percentage free  $1,25(\text{OH})_2\text{D}_3$  (also low-density-lipoprotein-related protein 2 or megalin may play a role).

Among subjects randomized to 20,000 IU vitamin  $\text{D}_3$  per week or placebo for 1 year, both serum total  $25(\text{OH})\text{D}$  and DBP were significantly lower among subjects with the DBP phenotype Gc2/Gc2 compared with other phenotypes, all of which included a Gc1S or Gc1F allele [265]. These levels were also lower in males than in females. Calculated or directly measured free  $25(\text{OH})\text{D}$  levels, while still lower among individuals with the Gc2/Gc2 phenotype, were not statistically significant from the other phenotypes. It should be noted that all participants in this study had vitamin D levels well within the normal range so the clinical significance of these differences is not clear. However, there may be situations such as cirrhosis or nephrotic syndrome where measurement of free metabolites may be important to avoid vitamin D toxicity when supplementation is instituted. Thus, in this context, the binding proteins of the vitamin D metabolites not only serve a transport function but also may provide a buffering mechanism to protect against toxicity [266].

## 5. Clinical manifestations of vitamin D toxicity

The clinical manifestations of vitamin D toxicity result primarily from hypercalcemia and reflect the

essential role of calcium in many tissues and targets, including bone, the cardiovascular system, nerves, and cellular enzymes. Initial signs and symptoms of hypervitaminosis D may be similar to other hypercalcemic states and include generalized weakness and fatigue. Central nervous system features may include confusion, difficulty in concentration, drowsiness, apathy, and coma [267]. Neuropsychiatric symptoms include depression and psychosis, which resolve following improvement of the hypercalcemia.

Hypercalcemia can affect the gastrointestinal tract and cause anorexia, nausea, vomiting, abdominal pain, and constipation. It can also induce hypergastrinemia. There is no evidence that peptic ulcers are more common than in any other form of hypercalcemia. Rarely, pancreatitis may be a presentation of either acute or chronic hypercalcemia.

In the heart, hypercalcemia may shorten the repolarization phase of conduction reducing the Q–T interval on the electrocardiogram (EKG). EKG changes in vitamin D toxicity have been mistaken for myocardial ischemia [268]. A more accurate EKG indication of the level of hypercalcemia is the Q–T interval corrected for rate. Bradyarrhythmias and first-degree heart block have been described, but are rare. Hypercalcemia may potentiate the action of digitalis on the heart [269].

Renal function is affected because high concentrations of calcium alter the action of vasopressin on the renal tubules. The net result is reduced urinary concentrating ability and a form of nephrogenic diabetes insipidus. This usually presents as polyuria, but rarely is the volume as high as that associated with central diabetes insipidus. Symptoms may include polydipsia, which is an expected consequence of polyuria. Hypercalciuria is one of the earliest signs of vitamin D toxicity and precedes the occurrence of hypercalcemia. The initial hypercalciuria may be ameliorated as renal failure progresses because of reduced calcium clearance. The pathophysiology of hypercalcemia can be rapidly worsened when volume depletion develops. When reduced renal blood flow occurs, less calcium is presented to the renal glomerulus, less calcium is filtered and excreted, and hypercalcemia can rapidly progress. Renal impairment from the hypercalcemia is reversible if it is of short duration. Chronic, uncontrolled hypercalcemia can lead to deposition of calcium phosphate salts in the kidney and permanent damage with eventual nephrocalcinosis. In an investigation of vitamin D–induced nephrocalcinosis, Scarpelli and colleagues [270] noted that cell damage, specifically in mitochondria, preceded intracellular calcium deposition. The hypercalcemia induced in rats by excessive vitamin D administration caused mitochondrial swelling, cell injury, and subsequent calcification.

Ectopic soft-tissue calcification can be a particular problem in hypervitaminosis D. The tendency toward soft-tissue calcification is compounded by the combination of hypercalcemia and hyperphosphatemia, often exceeding the solubility product of the two ions [271–273]. In rats exposed to excessive vitamin D, Hass and colleagues demonstrated that the pathological processes of vitamin D toxicity were related to dosage, length of time between doses, and duration of exposure [274]. For rats subjected to sublethal doses, generalized calcinosis was seen after only 8 days, when a total of 300,000 units of ergosterol was administered. Pathologically, bones appeared more brittle than normal, with increased cortical bone resorption, increased numbers of osteoclasts, and reduced numbers of osteoblasts. Abnormal calcium deposits were noted in the aorta and its major branches, heart, kidney, muscle, and respiratory tract. The earliest evidence of hypervitaminosis D was in the proximal aorta. Muscle tissue was the least resistant to calcification, with the order of decreasing susceptibility being smooth muscle > cardiac muscle > skeletal muscle [275]. The liver, brain, and pituitary were not affected by high doses of vitamin D. Permanent dental changes have also been reported with hypervitaminosis D, including enamel hypoplasia and focal pulp calcification [276]. Bone mineral density can be decreased due to excessive bone resorption [272,277], changes that can be reversed when vitamin D levels return to normal [278].

### 5.1 Diagnosis of vitamin D toxicity

With modern assays for calciotropic hormones, PTH, 25(OH)D, and 1,25(OH)<sub>2</sub>D<sub>3</sub>, one can readily differentiate vitamin D metabolite-mediated hypercalcemia from other causes of hypercalcemia. The circulating intact PTH level, measured by the two-site immunoradiometric assay (IRMA) or immunochemiluminometric assay (ICMA), should be suppressed in virtually all hypercalcemic disorders with the exception of primary hyperparathyroidism, familial hypocalciuric hypercalcemia, administration of lithium or thiazides, and renal failure. Although patients with malignancy-associated hypercalcemia tend to have a higher serum calcium concentration than those with other causes of hypercalcemia, diminished glomerular filtration rate and subsequent reduction in renal calcium excretion can dramatically increase the serum calcium level in any hypercalcemic patient. In contrast to the low serum phosphorus level in patients with hypercalcemia due to PTH or PTHrP, the serum phosphorus level is at the upper limit of normal or frankly elevated in patients with vitamin D metabolite-mediated hypercalcemia. This is due to increased intestinal absorption and reduced renal clearance of phosphate. An elevated 25(OH)D concentration with normal

1,25(OH)<sub>2</sub>D<sub>3</sub> level is indicative of toxicity with exogenously administered vitamin D or 25(OH)D. The serum 1,25(OH)<sub>2</sub>D level may be normally increased in patients with primary hyperparathyroidism due to the induction of renal 1 $\alpha$ -OHase by PTH. Abnormally high 1,25(OH)<sub>2</sub>D<sub>3</sub> levels, in the setting of suppressed PTH and hypercalcemia, indicate dysregulated production of 1,25(OH)<sub>2</sub>D<sub>3</sub> due to either granulomatous diseases, lymphoma, or toxicity with exogenous 1,25(OH)<sub>2</sub>D<sub>3</sub> or 1 $\alpha$ -OHD. In cases of hypercalcemia due to PTHrP or local osteolytic factors, the serum 1,25(OH)<sub>2</sub>D<sub>3</sub> concentration may be suppressed, but the determinant here is not so much the PTHrP, which stimulates the 1 $\alpha$ -OHase but rather the extent of the hypercalcemia that suppresses the 1 $\alpha$ -OHase. In patients with hypercalcemia due to toxicity with other vitamin D analogs such as dihydrotachysterol (DHT) [279] and calcipotriol, the active metabolites may not be recognized by the antibodies used in the conventional assays for 1,25(OH)<sub>2</sub>D<sub>3</sub>.

The diagnosis of vitamin D toxicity can be made on clinical grounds. Detailed clinical and drug history are of paramount importance to make an early diagnosis. Most patients who are suffering from vitamin D toxicity are taking vitamin D for osteoporosis, hypoparathyroidism, pseudohypoparathyroidism, hypophosphatemia, osteomalacia, or renal osteodystrophy in excessive dosages or at too frequent dosing intervals. With the recent idea that vitamin D is protective of many diseases, vitamin D therapy is becoming very widespread in otherwise normal subjects. Therefore, one should have a high index of suspicion in patients who are being treated with pharmacological dosages of vitamin D or its metabolites. History should be obtained to rule out use of over-the-counter supplements such as Soladek, which may contain suprapharmacologic amounts of vitamin D at manufacturer-recommended dosages.

Patients with granulomatous diseases or lymphoma usually have widespread active disease when hypercalcemia develops. In such cases, the diagnosis is obvious at the time of presentation. However, exceptions do exist. In patients with unexplained hypercalcemia, if the 1,25(OH)<sub>2</sub>D<sub>3</sub> level is elevated and other more easily identifiable causes for this elevation such as primary hyperparathyroidism, pregnancy, and exogenous toxicity (by history) are excluded, measurement of angiotensin-converting enzyme level and a systemic search for lymph node enlargement, pulmonary, renal, hepatosplenic, ocular, central nervous system, and bone marrow granulomas or lymphoma should be made.

### 5.2 Treatment of vitamin D toxicity

Dietary calcium and vitamin D restriction and avoidance of exposure to sunlight and other ultraviolet light

sources should be advised to patients at high risk to develop vitamin D metabolite-mediated hypercalcemia. Those at risk include patients with granulomatous diseases and lymphoma whose disease is widespread and active and patients who are already hypercalciuric. Fluid intake should be encouraged. Daily dietary calcium intake should be minimized to approximately 400 mg or less in these patients. Any use of vitamin D supplements should be discontinued. The patient should be encouraged to use sunscreen (sun protection factor [SPF] > 15) as much as possible when outdoors. The calcium level should be monitored closely in patients who have a previous history of hypercalcemia or hypercalciuria, or who have recently taken diets enriched in vitamin D and calcium, or who have a recent history of excessive sunlight exposure. A reduction in oxalate intake may also be advisable, so as to prevent an increase in oxalate absorption and hyperoxaluria, which may increase the risk of kidney stone formation, despite a reduction in urinary calcium excretion [280]. Patients with isolated hypercalciuria without other indications for corticosteroid therapy can be considered for a therapeutic trial of a thiazide diuretic. Thiazide diuretics inhibit calcium excretion from the distal convoluted tubule and have been shown to decrease the risk of

recurrent nephrolithiasis in idiopathic hypercalciuria [281,282]. However, thiazide can increase circulating levels of calcium, by this mechanism.

When hypercalcemia develops, the aforementioned preventive measures will help to ameliorate the severity of hypercalcemia. Treatment measures are summarized in Table 81.2. Treatment of the underlying disease process is essential. General measures in those who are symptomatic include hydration with normal saline followed by the judicious use of a loop diuretic, like furosemide, in certain cases. As hypercalcemia induces volume depletion, it should be ensured that the patient is volume replete, even nearing volume overload, prior to administering furosemide. Specific inhibitors of bone resorption, such as bisphosphonates [272,277] and calcitonin, can be helpful.

Glucocorticoids have proved to be particularly effective in vitamin D intoxication, granulomatous diseases, and lymphoma. The precise mechanism of action of glucocorticoids in calcium homeostasis is not known. Nonetheless, they are useful because they (1) directly inhibit gastrointestinal absorption of calcium by decreasing the synthesis of calcium-binding protein (calbindin-D) and may downregulate intestinal VDR [283] and decrease active transcellular transport [284],

**TABLE 81.2** Treatment of vitamin D toxicity.

Intervention	Mechanism of action	Onset of action	Duration of action
<i>First-line treatments</i>			
Treatment of the underlying disease process	Variable	Variable	Variable
Isotonic intravenous saline	Restoration of intravascular volume Increases urinary calcium excretion	Within hours	During infusion
Loop diuretics	Increase urinary calcium excretion via inhibition of calcium reabsorption in the loop of henle	Within hours	During therapy
Glucocorticoids	Decrease intestinal calcium absorption Decrease 1,25-dihydroxyvitamin D production by activated mononuclear cells May alter hepatic vitamin D metabolism to favor the production of inactive vitamin D metabolites In some cases, direct anti-tumor effect (e.g., lymphomas, multiple myeloma)	2–5 days	Days to weeks
<i>Second-line treatments</i>			
Bisphosphonates	Inhibit bone resorption via interference with osteoclast function	24–72 h	2–4 weeks
Ketoconazole, fluconazole	Decrease 1,25-dihydroxyvitamin D production by activated mononuclear cells through inhibition of cytochrome P450	2–4 days	During therapy
Aminoquinolones (chloroquine and hydroxychloroquine)	Decrease 1,25-dihydroxyvitamin D production by activated mononuclear cells through unknown mechanism in granulomatous disease (shown to be ineffective in lymphoma)	Days to weeks	During therapy

Adapted from Ref. [298].

(2) increase urinary excretion of calcium [285], and (3) may alter hepatic vitamin D metabolism to favor the production of inactive vitamin D metabolites, resulting in lower concentrations of 25(OH)D [286]. Evidence also suggests that they may increase the degradation of 1,25(OH)<sub>2</sub>D<sub>3</sub> at the receptor sites [287]. Glucocorticoids may also limit osteoclastic bone resorption [288]. Institution of glucocorticoid therapy results in prompt decline of the circulating 1,25(OH)<sub>2</sub>D<sub>3</sub> concentrations within 3–4 days [101]. Patients with nonhematological malignancies and those with primary hyperparathyroidism do not usually respond to glucocorticoids.

Aminoquinolones (chloroquine and hydroxychloroquine) are also capable of reducing the 1,25(OH)<sub>2</sub>D<sub>3</sub> and calcium concentrations in patients with sarcoidosis [289–292]. The theoretical advantage of aminoquinolones over glucocorticoids is that correction of the 1,25(OH)<sub>2</sub>D<sub>3</sub> should result in recovery of at least some of the bone density lost to the disease without the countervailing adverse skeletal effects of glucocorticoids [278]. In lymphoma cells, however, aminoquinolones do not have the same regulatory effects on the excess 1,25(OH)<sub>2</sub>D<sub>3</sub> as they do in granulomatous disease. In the presence of lymphoma, it is preferable to use glucocorticoid-containing antitumor regimens [293]. Owing to the limited experience with aminoquinolone drugs as antihypercalcemic agents and their potential side effects, they should be reserved for patients in whom steroid therapy is unsuccessful or specifically contraindicated. Ketoconazole, an antifungal agent, in high dosages can inhibit the mitochondrial cytochrome P450-linked 25(OH)D 1 $\alpha$ -OHase irrespective of whether it is renal [279] or extrarenal as in sarcoidosis [294] and tuberculosis [141]. Case reports of ketoconazole use in conjunction with glucocorticoids in sarcoidosis suggest that the addition of ketoconazole may reduce steroid requirements [295,296]. Ketoconazole has been used successfully to decrease the hypercalcemia, hypercalciuria, and elevated serum 1,25(OH)<sub>2</sub>D<sub>3</sub> levels in patients with CYP24A1 mutations [229,297]. Use of ketoconazole is often limited by hepatic side effects and adrenal insufficiency unless used concomitantly with glucocorticoids. Fluconazole has also been described for treatment and may be effective at low doses [232].

## 6. Conclusions

Vitamin D toxicity is not a common cause of hypercalcemia, but it can be life-threatening if not identified promptly. When the two major etiologies of hypercalcemia, primary hyperparathyroidism and malignancy, are excluded, vitamin D toxicity becomes an important diagnostic consideration. There are many forms of exogenous

and endogenous vitamin D toxicity. Inadvertent excessive use of pharmaceutical preparations is the most common cause of exogenous toxicity. Excessive amounts of the parent compound, vitamin D, can be most difficult to manage as compared with toxicity due to the metabolites 25(OH)D or 1,25(OH)<sub>2</sub>D<sub>3</sub>. Extensive lipid solubility of vitamin D accounts for its long half-life and tendency for prolonged hypercalcemia. New clinical applications of 1,25(OH)<sub>2</sub>D<sub>3</sub> and its synthetic analogs have been accompanied by the increased potential for toxicity. Endogenous etiologies may result from ectopic production of 1,25(OH)<sub>2</sub>D<sub>3</sub> in multiple diseases including sarcoidosis, tuberculosis, rarer granulomatous conditions, inflammatory reactions to foreign bodies, or in lymphoma. Genetic testing has discovered mutations in the CYP24A1 gene responsible for decreased clearance of 1,25(OH)<sub>2</sub>D<sub>3</sub>, which can lead to hypercalcemia. Many different mechanisms have been proposed to account for vitamin D toxicity, including the vitamin D metabolite itself, VDR number, activity of 1 $\alpha$ -OHase, inhibition of vitamin D metabolism, and the capacity of DBP to bind vitamin D metabolites. Mounting evidence that higher levels of vitamin D may have beneficial effects on bone and cellular health may predispose to enhanced administration of vitamin D in the future and thereby increased frequency of vitamin D toxicity.

## 7. Summary points

- Exogenous vitamin D toxicity is a result of excessive intake of parent vitamin D, its metabolites, or vitamin D analogs.
- Endogenous vitamin D toxicity may result from ectopic production of 1,25(OH)<sub>2</sub>D<sub>3</sub> in multiple diseases or from decreased clearance of 1,25(OH)<sub>2</sub>D<sub>3</sub> in the setting of CYP24A1 gene mutations.
- Different proposed mechanisms of vitamin D toxicity include metabolites of vitamin D, vitamin D receptor concentrations, activity of 1 $\alpha$ -OHase, inhibition of vitamin D metabolism, and the capacity of vitamin D-binding protein.
- The clinical manifestations of vitamin D toxicity result primarily from hypercalcemia, and the diagnosis can be made based on the clinical history and measurement of PTH, 25(OH)D, and 1,25(OH)<sub>2</sub>D<sub>3</sub> levels.
- Initial treatment of hypercalcemia due to vitamin D toxicity includes restricting dietary intake of vitamin D and calcium, withholding supplementations, and hydration with isotonic saline. Depending on the exact mechanism, loop diuretics, bisphosphonates, calcitonin, glucocorticoids, aminoquinolones, and ketoconazole may also be added for management.

# Vitamin D and Paget's disease

Noriyoshi Kurihara and G. David Roodman

Indiana University, Indianapolis, IN, United States

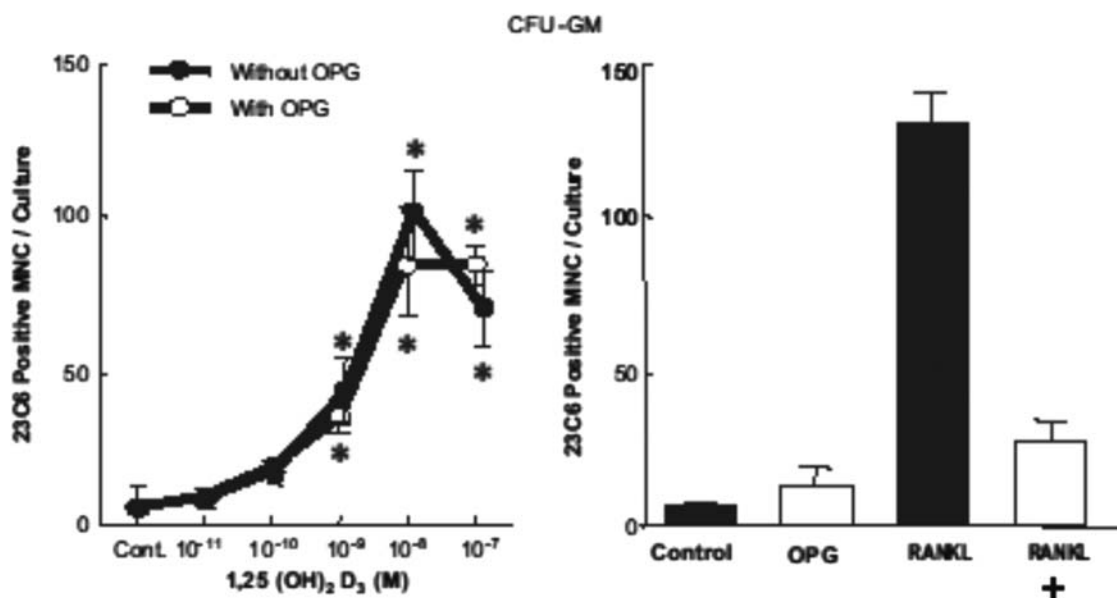

## OBJECTIVES

- Expression of TAF 12 in osteoclast precursors from Paget's disease (PD) patients contributes to their hyperresponsivity to low concentrations of  $1,25(\text{OH})_2\text{D}_3$
- Understanding the mechanisms responsible for the increased vitamin D responsivity of OCL precursors from patients with PD, and the effects of VDR-mediated transcription on OCL activity in PD.
- Understand the importance of correcting low serum concentrations of vitamin D and the occurrence of acute phase reactions (APR) to bisphosphonates in PD patients

## 1. Introduction

Paget's disease (PD) is a common bone disorder that was originally described by Sir James Paget over 100 years ago [1]. PD is characterized by highly localized areas of bone resorption coupled with exuberant new bone formation. Bone lesions in PD contain markedly increased numbers of abnormal osteoclasts (OCLs) and large numbers of osteoblasts that rapidly form new bone in response to the increased bone resorption. The bone that is formed in PD is highly abnormal woven bone and is of poor quality because of the rapid bone formation. However, the OCL is the primary cell involved in the pathogenesis of PD. OCLs in PD lesions are increased in number and size [2] and contain up to

100 nuclei per OCL. In contrast, normal human OCL contains between 3 and 10 nuclei per osteoclast. Pagetic OCLs also contain paramyxoviral inclusions [3] that are not present in other bone marrow cells or in nonpagetic bones of these patients. Further, several studies have shown that these nuclear inclusions cross-react with antibodies to the respiratory syncytial virus and/or measles virus nucleocapsid proteins. Abe and coworkers also found the budding-off of viral particles from pagetic OCLs [4]. These results suggested a possible viral etiology for PD. We previously showed that pagetic OCLs from 70% of PD patients we tested contain measles virus (MV) transcripts [5], and demonstrated that OCL formed by normal human OCL precursors transfected with the measles virus nucleocapsid protein gene (MVNP) have many of the features of pagetic OCL, including responsivity to  $1,25(\text{OH})_2\text{D}_3$  and rank ligand (RANKL), production of high levels of IL-6 and TAF12, a vitamin D nuclear receptor (VDR) coactivator [6]. However, there is a strong genetic component also involved [7] with about 30% of patients having an affected first-degree relative, and large kindreds of Paget's patients have been reported. Interestingly, OCL formed in marrow cultures from PD patients harboring mutations linked to PD but not expressing MVNP, are hyperresponsive to RANKL but not to  $1,25(\text{OH})_2\text{D}_3$  [8], and do not express high levels of TAF12 [8]. However, marrow stromal cells from PD patients harboring the  $\text{p62}^{\text{P392L}}$  mutations express high levels of TAF12 and produce increased amounts of RANKL in response to  $1,25(\text{OH})_2\text{D}_3$ . In this chapter, we will focus on the mechanisms responsible for the increased vitamin D responsivity of OCL precursors from patients with PD and the effects of VDR-mediated transcription on OCL activity in PD.

**FIGURE 82.1** Osteoprotegerin (OPG) does not inhibit osteoclast (OCL) formation in cultures of purified human OCL precursors. Highly purified OCL precursors (CFU-GM) that do not contain stromal cells from normal donors ( $10^6$  cells/well) were cultured with  $1,25(\text{OH})_2\text{D}_3$  ( $10^{-11}$ – $10^{-7}$  M) or rank ligand (RANKL) (50 ng/mL) in the presence or absence of OPG (50 ng/mL). After 2 weeks, the cells were fixed and stained with the 23C6 monoclonal antibody, which identifies OCLs. The results are expressed as mean  $\pm$  SD for quadruplicate cultures. \*,  $P < .05$  compared to control lacking added  $1,25(\text{OH})_2\text{D}_3$ . CFU-GM, granulocyte–macrophage colony-forming unit; SD, standard deviation

## 2. Mechanism of action of $1,25(\text{OH})_2\text{D}_3$ on osteoclast formation

Vitamin D plays a major role in bone homeostasis.  $1,25(\text{OH})_2\text{D}_3$ , the active form of vitamin D<sub>3</sub>, binds the classical VDR in the cytoplasm at high affinity, and the complex then translocates to the nucleus.  $1,25(\text{OH})_2\text{D}_3$  promotes heterodimerization of VDR with the retinoid receptor, which recruits coactivators and releases corepressors from vitamin D response element (VDRE) present in the promoters of vitamin D target genes. The VDR-associated coactivators then recruit the transcription factor TFIID multiprotein complex, composed of TATA-binding protein (TBP) and a series of TBP-associated factors (TAFs), which in turn recruit the RNA Pol II transcription complex to the promoter. Formation of this complex results in transcription of vitamin D-responsive genes [9–12].

$1,25(\text{OH})_2\text{D}_3$  has several important effects on bone remodeling. Among these, it enhances calcium (Ca) absorption through the gut, and it increases RANKL production and suppresses osteoprotegerin (OPG) expression by marrow stromal cells and osteoblasts. We showed that OCL precursors express VDR [13] and found that  $1,25(\text{OH})_2\text{D}_3$  may directly stimulate human OCL precursors to form OCLs. This conclusion is based on our findings that OCL formation by unfractionated normal human bone marrow mononuclear cells treated with  $1,25(\text{OH})_2\text{D}_3$  can only be partially inhibited by OPG. In contrast, when these marrow cultures are

treated with RANKL rather than  $1,25(\text{OH})_2\text{D}_3$ , OPG totally inhibits OCL formation. Further, OPG does not affect OCL formation by highly purified normal human OCL precursors that do not contain stromal cells, treated with  $1,25(\text{OH})_2\text{D}_3$ . In contrast, OPG totally blocks OCL formation when these highly purified human OCL precursors are treated with RANKL. These results demonstrate that  $1,25(\text{OH})_2\text{D}_3$  stimulates human OCL formation in human marrow cultures both directly and indirectly through its capacity to induce RANKL (Fig. 82.1).

## 3. Increased levels of TAF12 in osteoclast precursors from Paget's disease patients contribute to their hyperresponsivity to $1,25(\text{OH})_2\text{D}_3$

One of the earliest findings in our studies of OCL formation in PD was that OCL precursors from Paget's patients were hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$  and formed OCL-like cells in marrow culture at concentrations of  $1,25(\text{OH})_2\text{D}_3$  that were at least 1–2 logs less than those required for OCL formation in normal marrow cultures [13]. We found, using highly purified populations of early OCL precursors from Paget's patients, that the high responsivity of OCL precursors to  $1,25(\text{OH})_2\text{D}_3$  appeared to be an intrinsic property of early OCL precursors, the granulocyte–macrophage colony-forming unit (CFU-GM)–derived cells [14].

However, the mechanism responsible for the enhanced  $1,25(\text{OH})_2\text{D}_3$  responsiveness of these early precursors was unknown. We showed that the enhanced sensitivity of pagetic OCL precursors was not because of increased VDR numbers [15], and thought it was unlikely that Paget's patients have a mutated VDR that has an intrinsically increased affinity for  $1,25(\text{OH})_2\text{D}_3$ . This conclusion was based on multiple reports that although mutations that predispose to PD have been identified on more than six different chromosomal loci, none of these coincide with the chromosomal location of VDR. Further, the majority of PD patients who do not have a genetic predisposition to PD appear to have OCL precursors that are hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$ .

To investigate the mechanisms responsible for the enhanced  $1,25(\text{OH})_2\text{D}_3$  responsiveness of PD OCL precursors, we incubated a GST (glutathione s-transferase)–VDR chimeric protein with lysates from marrow cells of involved bone from PD patients [16,17] and isolated TAF12 (formerly termed TAF<sub>II</sub>-17). Transduction of TAF12 into NIH3T3 cells, specifically increased VDR transcriptional activity. Furthermore, mammalian two-hybrid studies showed that TAF12 bound VDR and enhanced VDR-mediated transcription [18], demonstrating that TAF12 acted like a novel VDR coactivator.

TAF12 is a member of the TFIID transcription complex that was thought to be only responsible for promoter recognition and directing RNA Pol II to core promoters in response to activators of transcription [19,20]. This function of TFIID was considered universal rather than gene-specific because TFIID is expressed in all tissues. However, several studies suggested that different combinations of TAFs are mobilized in response to different growth stimuli and that some TAFs (e.g., TAF4, TAF7, TAF10, and TAF11) can act as specific coactivators of genes [21]. The histone fold domains of TAFs play a critical role in their physical association with gene promoters. These domains interact to form heterodimers between particular pairs of TAFs (e.g., TAF4 and TAF12), which associate to form histone octamer–like substructures that bind to core promoters. Interestingly, TFIID components can be cell–type-specific and regulate specific genes. For example, TAF4b (formerly TAF<sub>II</sub>-105 and a TAF4 paralogue) is highly expressed in the testes and ovary and regulates the transcription of specific genes in granulosa cells. Mice lacking TAF4b are sterile [22]. Other alternate forms of the TFIID transcription complex have also been shown to act as selective activators of cell–type-specific gene expression required for cell differentiation. For example, in *Drosophila* five tissue-specific TAF paralogues have been detected for TAFs 4, 5, 6, 8, and 12 [23]. TAF4 and TAF12 interact structurally and can regulate a testis-specific gene expression program in primary spermatocytes required for their terminal

differentiation [23]. Similarly, TAF3 and TRF3 can act as a novel core transcription complexes for the differentiation of myoblasts to myotubules [24]. These results support the notion that TAF12 may play an important role in tissue-specific gene expression involved in OCL differentiation.

### 3.1 Measles virus infection of osteoclast precursors induces TAF12

To determine if MV infection increased the responsiveness of OCL precursors to  $1,25(\text{OH})_2\text{D}_3$  and resulted in upregulation of TAF12, a cellular MV receptor, human CD46, was targeted to cells in the OCL lineage in transgenic mice using the mouse tartrate-resistance acid phosphatase (TRACP) gene promoter. Targeting hCD46 to murine cells allows MV infection. The MV-infected cells were hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$  and expressed TAF12. OCLs formed by MV-infected marrow cells from TRACP–CD46 mice expressed several characteristics of pagetic OCLs [25]. These results suggest that MV infection of OCL precursors can induce TAF12.

### 3.2 Transgenic mice with tartrate-resistance acid phosphatase–driven measles virus nucleocapsid gene expression in OCLs also express TAF12

Because we found that OCLs from patients with PD expressed MVNP, we then determined if the persistent expression of the MVNP gene could induce changes in the bone similar to those found in PD. The MVNP gene was targeted to cells in the OCL lineage in transgenic mice using the TRACP promoter. These mice developed bone abnormalities similar to those seen in PD at 4–16 months of age (TRACP–MVNP mice) [26]. Significantly increased numbers of OCLs were formed in marrow cultures from TRACP–MVNP mice compared to marrow cultures from WT mice treated with  $1,25(\text{OH})_2\text{D}_3$ . Further, TRACP–MVNP marrow cultures formed OCLs at concentrations of  $1,25(\text{OH})_2\text{D}_3$  that were significantly lower than those required for WT marrow cultures, with OCL formation occurring in MVNP cultures at  $10^{-11}$ – $10^{-12}$  M  $1,25(\text{OH})_2\text{D}_3$ . In addition, the OCL precursors from TRACP–MVNP, but not WT mice, expressed high levels of TAF12 mRNA. Finally, the number of nuclei per OCL was also significantly increased in marrow cultures from TRACP–MVNP mice compared to WT mice, and the OCLs that formed were larger than those formed in WT marrow cultures.

### 3.3 Transduction of an antisense measles virus nucleocapsid protein construct into osteoclast precursors from patients with Paget's disease also reduced expression of TAF12

To examine if TAF12 expression was required for the  $1,25(\text{OH})_2\text{D}_3$  hyperresponsivity of PD OCL precursors, we determined the effects of transducing an antisense MVNP construct (AS-MVNP) into OCL precursors from patients with PD on OCL formation. Transfection of MVNP-expressing OCL precursors with an AS-MVNP construct decreased expression of MVNP mRNA by nearly 70% and resulted in an 80% reduction in TAF12 expression, levels as well as significant reductions in OCL formation, nuclei/OCL, and IL-6 production induced by  $1,25(\text{OH})_2\text{D}_3$ , as compared to cells transfected with the scrambled control antisense construct (AS-CONT) [27]. The OCLs that formed by the AS-MVNP transduced PD patient-derived OCLs were not hypernucleated. AS-MVNP also inhibited the increased bone resorption by OCLs formed in marrow cultures from MVNP-expressing PD patients when compared with normal OCLs. AS-MVNP had no effect on OCL formation, OCL morphology, bone resorption, or IL-6 production by PD patients with a mutation in p62, linked to PD, but not expressing MVNP or normal OCL precursors [27].

### 3.4 Effects of IL-6 on TAF12 expression by osteoclast precursors

IL-6 levels are markedly increased in OCL precursors from patients with PD [28] and MVNP-transduced normal OCL precursors. IL-6 is also a major mediator of human OCL formation, and high levels of IL-6 can induce hypermultinucleated OCLs that display many of the features of pagetic OCLs [29] and can induce TAF12 mRNA in normal OCL precursors. Further, treatment of pagetic OCL precursors with an antibody to IL-6 decreases OCL formation [30].

To further investigate the role of IL-6 in TAF12 expression by OCL precursors, we targeted the overexpression of IL-6 to the OCL lineage in transgenic mice using the TRACP promoter. TRACP-IL-6 mice expressed twofold higher levels of IL-6 [31], and the OCL precursors were hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$ . Measurement of TAF12 expression in TRACP-IL-6 mice demonstrated that TAF12 levels were increased approximately twofold compared with wild-type (WT) littermates. To further assess the role of IL-6 in  $1,25(\text{OH})_2\text{D}_3$  responsivity of OCL precursors, TRACP-MVNP mice, which express a pagetic phenotype and high levels of IL-6, were bred to IL-6<sup>-/-</sup> mice [32]. In contrast to MVNP mice, OCL

precursors from MVNP/IL-6<sup>-/-</sup> mice were not hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$ , expressed low levels of TAF12 and formed OCL that contained a similar number of nuclei/OCL as WT mice and did not express a pagetic phenotype. These results demonstrate that IL-6 induces many of the effects of MVNP on OCL formation.

Thus, loss of IL-6 expression in TRACP-MVNP mice decreased TAF12 expression, reversed the hyperresponsivity of OCL precursors to  $1,25(\text{OH})_2\text{D}_3$  and resulted in the loss of the pagetic phenotype in OCLs formed in marrow cultures from these mice [27]. These results demonstrate that IL-6 upregulates TAF12 in OCL precursors, and that loss of IL-6, even when MVNP is present in these OCL precursors, results in loss of TAF12 expression.

### 3.5 Overexpression of TAF12 is sufficient to induce $1,25(\text{OH})_2\text{D}_3$ hyperresponsivity in human osteoclast precursors

To further assess the role of TAF12 in OCL formation, we determined the effects of overexpression of TAF12 in normal human OCL precursors. These experiments allowed a direct determination of the capacity of increased levels of TAF12 to mediate  $1,25(\text{OH})_2\text{D}_3$  hypersensitivity in OCL precursors in vitro and to determine the contribution of TAF12 to the development of pagetic-like OCLs.

The cDNA for TAF12 was synthesized by RT-PCR from OCL precursor cells of PD patients and inserted into a retroviral construct [33]. The TAF12-expressing virus was transduced into normal human marrow cells. TAF12-transduced normal OCL precursors expressed twofold higher TAF12 mRNA levels compared with empty vector (EV)-transduced OCL precursors. In addition, an MVNP-retrovirus construct was transduced into human nonadherent mononuclear cells to compare TAF12 overexpressing OCL precursors with MVNP-expressing OCLs. The OCL precursors were treated with  $10^{-11}$ – $10^{-7}$   $1,25(\text{OH})_2\text{D}_3$ , and the number and characteristics of the OCLs formed and levels of CYP24A1 mRNA were determined and compared with EV-transduced OCLs. The TAF12-transduced cells formed increased numbers of OCLs that were hypersensitive to  $1,25(\text{OH})_2\text{D}_3$ , but in contrast to MVNP-expressing cells, did not contain increased numbers of nuclei per OCL or produce high levels of IL-6 ( $47 \pm 1$  pg/mL vs.  $269 \pm 11$  pg/mL, TAF12- vs. MVNP-transduced cells) [34]. Similarly, the EV-transduced cells did not produce detectable levels of IL-6. We then compared the bone-resorbing capacity of TAF12-transduced OCL precursors treated with  $1,25(\text{OH})_2\text{D}_3$  to MVNP-transduced OCL precursors. OCLs formed by MVNP-transduced OCL precursors treated with

$1,25(\text{OH})_2\text{D}_3$  had a markedly increased bone-resorbing capacity per OCL. In contrast, the bone resorption capacity per OCL formed by TAF12-transduced OCL precursors was similar to those from EV-transduced OCL precursors. These results strongly suggested that increased TAF12 expression is not sufficient to induce a pagetic phenotype in OCLs but is sufficient to induce hyperresponsivity to  $1,25(\text{OH})_2\text{D}_3$  in OCL precursors.

### 3.6 Osteoclast precursors from TRACP–TAF12 transgenic mice are hyperresponsive to $1,25(\text{OH})_2\text{D}_3$

To further characterize the contribution of TAF12 to OCL formation in PD, we generated TRACP–TAF12 transgenic mice in which TAF12 expression is targeted to the OCL lineage with the TRACP promoter. When bone marrow cells from TRACP–TAF12 and TRACP–MVNP mice were cultured with  $1,25(\text{OH})_2\text{D}_3$ , OCLs formed at low concentrations ( $10^{-10}$  M) of  $1,25(\text{OH})_2\text{D}_3$ , a concentration that does not induce OCL formation in marrow cultures from WT mice. OCLs formed from TRACP–MVNP marrow exhibited markedly elevated nuclear numbers per OCL in response to  $1,25(\text{OH})_2\text{D}_3$ , but the nuclear number per OCL in TRACP–TAF12 mice was similar to WT OCLs. To determine if these OCL precursors demonstrated enhanced VDR-mediated transcription at low concentrations of  $1,25(\text{OH})_2\text{D}_3$ , we measured the expression of *CYP24A1* in response to varying concentrations of  $1,25(\text{OH})_2\text{D}_3$ . OCL precursors from both TRACP–MVNP and TRACP–TAF12 mice showed increased *CYP24A1* expression compared with OCL precursors from WT mice when treated with low concentrations of  $1,25(\text{OH})_2\text{D}_3$ . IL-6 production by OCL precursors treated with  $1,25(\text{OH})_2\text{D}_3$  was also increased in both TRACP–MVNP and TRACP–TAF12 OCL precursors compared with WT mice but to a lesser extent in the TRACP–TAF12 derive cells. Histomorphometric analysis of bones from TRACP–TAF12 mice showed only mild increases in OCL formation and no morphologic changes in characteristics of PD [34].

### 3.7 Effects of transduction of a TAF12 antisense construct on OCL formation in marrow cultures from PD patients expressing MVNP in their OCL precursors

To determine the contribution of TAF12 to the hyper-sensitivity to  $1,25(\text{OH})_2\text{D}_3$  in OCL precursors from PD patients, we transduced a retrovirus construct containing an antisense to TAF12 into MVNP-expressing OCL precursors from PD patients and healthy controls

because our previous studies showed that almost all MVNP-expressing OCL precursors from PD patients were hyperresponsive to  $1,25(\text{OH})_2\text{D}_3$  and expressed increased levels of TAF-12. The TAF12 antisense construct decreased TAF12 expression by more than 80%, as well as  $1,25(\text{OH})_2\text{D}_3$  hypersensitivity of the PD OCL precursors, to levels that were like the effects of antisense MVNP.

When MVNP-expressing Paget's patient CFU-GM was cultured for 14 days in the presence or absence of TAF12 antisense construct or a control antisense construct (AS-CONT) and treated with  $10^{-11}$ – $10^{-7}$  M  $1,25(\text{OH})_2\text{D}_3$ , OCL formation was decreased by 37%–64% by antisense TAF12 (Fig. 82.2). Thus, transfection of an antisense TAF12 construct into OCL precursors from PD patients expressing MVNP decreased their hypersensitivity to  $1,25(\text{OH})_2\text{D}_3$  [34].

## 4. Mechanism of action of TAF12 in the increased $1,25(\text{OH})_2\text{D}_3$ responsivity of OCL precursors from Paget's patients

### 4.1 TAF12 binds the *Cyp24A1* promoter in osteoclast precursors

The increased expression of TAF12 induced by the high IL-6 levels in MVNP-expressing OCL is one mechanism underlying their hyperresponsivity to  $1,25(\text{OH})_2\text{D}_3$  in PD. To further characterize the mechanisms responsible for the effects of TAF12 on  $1,25(\text{OH})_2\text{D}_3$  responsivity, we determined if TAF12 binds the *CYP24A1* promoter. Chromatin immunoprecipitation studies were performed on the *CYP24A1* promoter in both TRACP–MVNP and WT OCL precursors, using an anti-TAF12 antibody and primers flanking the two VDREs.  $1,25(\text{OH})_2\text{D}_3$  induced TAF12 binding to the *CYP24A1* promoter in TRAP–MVNP as well as WT OCL precursors, but with both basal and induced levels of TAF12 binding were much higher in the OCL precursors from TRACP–MVNP mice [34].

### 4.2 TAF12 interacts with ATF7

Several studies suggested that TAF12 is a functional partner of ATF7 and TAF4. ATF7 binds as a homodimer to cAMP response element sequences (TGACGTCA) and can also heterodimerize with members of the Jun and Fos families to bind TPA response element TRE sequences (TGACTCAG). Hamard and colleagues [35] reported that overexpressed TAF12 directly interacts with ATF7 and potentiates ATF7-induced transcriptional activation of ATF7-driven genes. Further, coimmunoprecipitation studies supported the physical interaction of

**FIGURE 82.2** Osteoclast (OCL) formation induced by  $1,25(\text{OH})_2\text{D}_3$  is reduced in cultures of antisense TAF12 (AS-TAF12) transduced human OCL precursors from Paget's disease (PD) patients but not from normals. AS-TAF12 or scrambled antisense-transduced OCL precursors from three PD patients or two normals were cultured in methylcellulose with recombinant GM-CSF and G418. G418-resistant CFU-GM-derived  $\text{CD}11\text{b}^+$  cells were then cultured with varying concentrations of  $1,25(\text{OH})_2\text{D}_3$  for 3 weeks. The cells were then fixed and stained with the 23C6 monoclonal antibody, which identifies OCL. The results represent the mean  $\pm$  SD of aggregate data from three MVNP<sup>+</sup> PD patients and two normals. \*,  $P < .01$  compared to scrambled antisense transduced cells. CFU-GM, granulocyte-macrophage colony-forming unit; GM-CSF, granulocyte-macrophage colony-stimulating factor; MVNP, measles virus nucleocapsid protein; SD, standard deviation

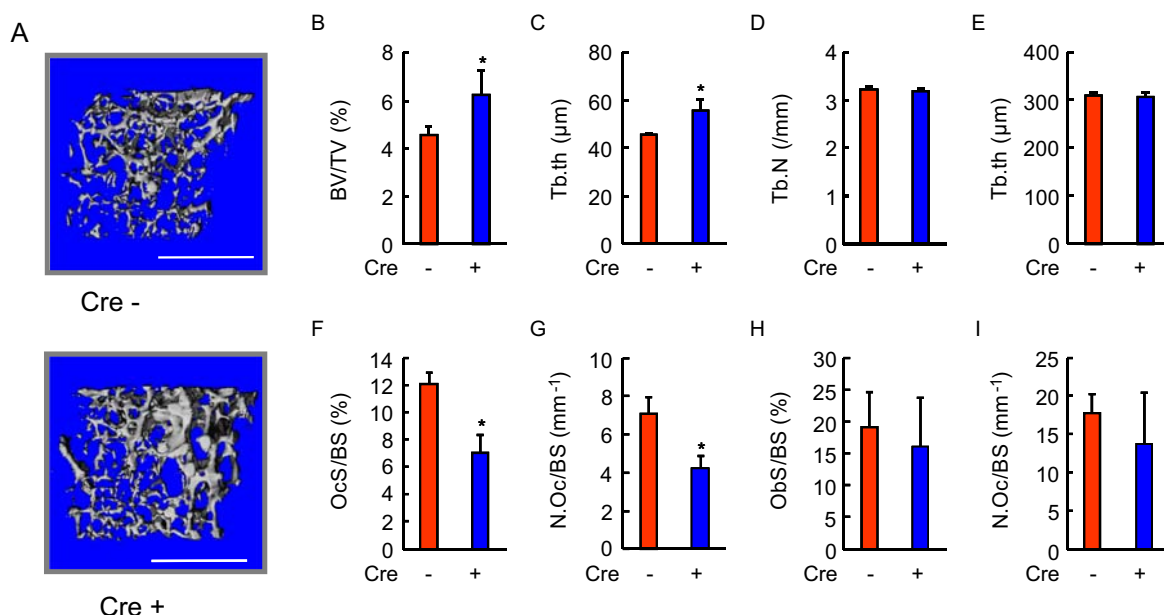

ATF7 with TAF12 on an ATF7-responsive promoter in the absence of overexpression of either protein. Importantly, TAF12-dependent ATF7-regulated transcriptional activation was competitively inhibited by TAF4, which binds both ATF7 and TAF12. ATF7, like TAF12, is also increased in OCL precursors from TRACP-MVNP mice and in MVNP-expressing NIH3T3 cells. High levels of ATF7 expression were detected in MVNP-expressing cell lysates and were not further increased by  $1,25(\text{OH})_2\text{D}_3$ . Expression of TAF4 was not affected by MVNP. Immunoprecipitation of lysates from either WT or TRACP-MVNP OCL precursors with an anti-TAF12 antibody followed by blotting with an anti-ATF7 antibody or vice versa revealed that TAF12 and ATF7 physically interact in OCL precursors. These results demonstrate that TAF12 and ATF7 physically interact in OCL precursors, and that the ratio of TAF12 to TAF4 is increased by MVNP. As noted above, a key VDR target gene, *CYP24A1*, is the first gene activated by VDR and deactivates  $1,25(\text{OH})_2\text{D}_3$  to control the transcriptional activity of VDR. We also found that knockdown of ATF7 decreased the sensitivity of *CYP24A1* to  $1,25(\text{OH})_2\text{D}_3$  as well as TAF12 levels in MVNP-expressing cells. Thus, the interaction of ATF7 with TAF12 may be involved in the upregulation of TAF12 and the hypersensitivity of OCL precursors to  $1,25(\text{OH})_2\text{D}_3$ .

### 4.3 TAF12 enhances vitamin D nuclear receptor content and half-life in cells

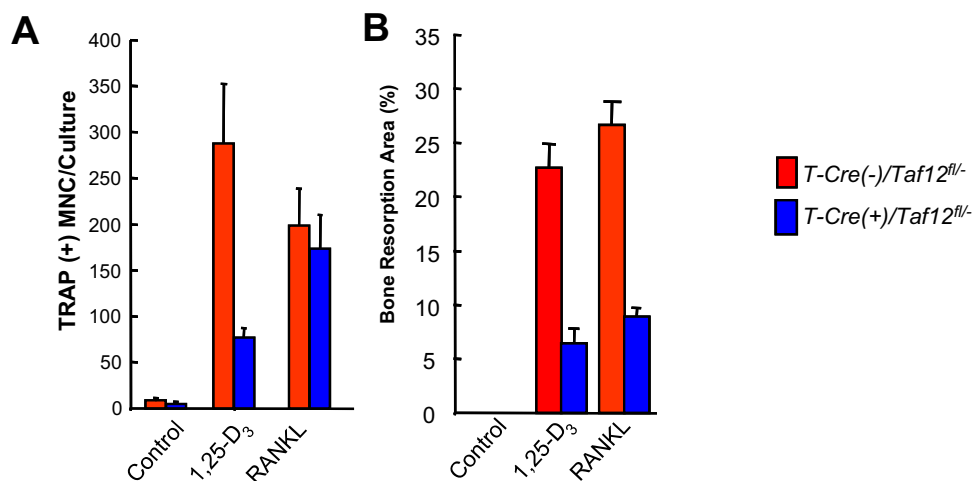

Because stabilization of the  $1,25(\text{OH})_2\text{D}_3$ -VDR complex by TAF12 and/or ATF7 is a potential mechanism for increased VDR responsiveness in MVNP-expressing cells [36], we measured VDR content by Western blot in MVNP-transfected NIH3T3 cells (MVNP-NIH3T3) and empty vector-transfected cells (EV-NIH3T3). We found that  $1,25(\text{OH})_2\text{D}_3$  increased VDR content in both cell types. Further, physiological concentrations of  $1,25(\text{OH})_2\text{D}_3$  ( $10^{-10}$  M) markedly enhanced the stability of VDR in MVNP-NIH3T3 cells that also expressed increased levels of TAF12. In contrast, high concentrations of  $1,25(\text{OH})_2\text{D}_3$  (over  $10^{-8}$  M) were required to enhance VDR stability in EV-NIH3T3 cells [34]. Moreover, hyperresponsivity of MVNP-NIH3T3 cells to  $1,25(\text{OH})_2\text{D}_3$  was diminished by transfection of TAF12 siRNA, which also decreased VDR content. Results obtained using bone marrow from TRACP-MVNP and TRACP-TAF12 mice demonstrated that when TAF12 expression was increased,  $1,25(\text{OH})_2\text{D}_3$  ( $10^{-12}$ – $10^{-7}$  M) markedly increased VDR content (Fig. 82.3). These results suggest that stabilization of the  $1,25(\text{OH})_2\text{D}_3$ -VDR complex may contribute to the hyperresponsivity of OCL precursors to  $1,25(\text{OH})_2\text{D}_3$  that overexpress TAF12 [34].

**FIGURE 82.4** *Trap-Cre(+)/Taf12<sup>fl/-</sup>* mice exhibit increased bone mass, and decreased bone resorption. (A) Representative micro-CT images of distal femur from mice at 12 months of age. Scale bar, 1 mm. (B–I) bone morphometric analysis of 8-month-old *Trap-Cre(-)/Taf12<sup>fl/-</sup>* (*n* = 3) and *Trap-Cre(+)/Taf12<sup>fl/-</sup>* (*Taf12cKO*) (*n* = 4) mice. BV/TV, bone volume per total volume; N.Oc/BS, osteoclast number per bone surface; N.Oc/BS, osteoclast number per bone surface; ObS/BS, osteoblast surface per bone surface; OcS/BS, osteoclast surface per bone surface; Tb.th, trabecular thickness; Tb.N, trabecular number; Tb.Sp, trabecular separation. **FIGURE 82.5** Osteoclast formation and bone resorption by *Trap-Cre/Taf12<sup>fl/-</sup>* OCLs. (A) Nonadherent marrow mononuclear cells were cultured with M-CSF (10 ng/mL) for 3 days, then the OCL precursors were cultured with 1,25-(OH)<sub>2</sub>D<sub>3</sub> or RANKL in  $\alpha$ -MEM containing 10% FCS for 4 days. The cells were then stained for TRACP. Cells with > 3 nuclei per cell were counted as OCL. The data are shown as mean ± SD (*n* = 3). \**P* < .01 compared with the same treatment of *Trap-Cre(-)/Taf12<sup>fl/-</sup>* marrow. (B) The enriched OCL cell fraction was cultured on dentin slices for 3 days. Then dentin slices were stained with hematoxylin after removing cells. The bone resorption area was counted using a grid and resorption area was evaluated resorption area/total dentin area.

ruffled border in OCLs [40], we examined the effects of loss of TAF12 on autophagic molecule expression in OCLs. We found that syntaxin17 expression, which is involved in autophagosome formation [41], was significantly lower on Western blots (Fig. 82.6) and by

immunohistochemistry of OCLs from TC(+)/Taf12 mice versus TC(-)/Taf12 mice (Fig. 82.7). These results suggest that TAF12 contributes to OCL differentiation, bone resorption, and CTSK secretion in vivo and may be a novel target for blocking bone resorption.

**FIGURE 82.6** Expression levels of cathepsin K, LC3, and syntaxin 17 in osteoclasts derived from *Trap-Cre/Taf12<sup>fl/-</sup>* mouse bone marrow cultures. Osteoclasts were isolated and treated with 1,25-(OH)<sub>2</sub>D<sub>3</sub> or RANKL in  $\alpha$ -MEM containing 10% FCS for 2 days. The cell lysates were collected and were assayed by Western blotting using cathepsin K, LC3 and STX17 antibodies.

## 7. Serum concentration of 1,25(OH)<sub>2</sub>D<sub>3</sub> in Paget's patients

We then determined if the increased responsiveness of pagetic OCL precursors to 1,25(OH)<sub>2</sub>D<sub>3</sub> altered vitamin D metabolism, the profile of vitamin D metabolites, Ca, and inorganic phosphate (Pi) by measuring these parameters in the sera of nine patients with PD and 10 age-matched normal healthy volunteers. The concentrations of Vitamin D metabolites, 25OH-D<sub>3</sub>, 24,25(OH)<sub>2</sub>D<sub>3</sub>, and 1,25(OH)<sub>2</sub>D<sub>3</sub>, Ca, and Pi in sera of patients with PD were almost identical to those of age-matched normal healthy volunteers. No abnormality in Vitamin D metabolism was detected in patients with PD. The concentrations of 1,25(OH)<sub>2</sub>D<sub>3</sub> in sera of patients with PD were  $41.0 \pm 9.1$  pg/mL serum ( $10^{-10}$  M) similar to that of age-matched normal healthy volunteers. These data suggest that there are

adequate levels of 1,25(OH)<sub>2</sub>D<sub>3</sub> in Paget's patients and that these levels should be sufficient to induce OCL formation in the pagetic lesions [42].

Specific treatments for PDB are aimed at increased OCL activity to reduce abnormal bone remodeling. Bisphosphonates (BPs) are currently considered the treatment of choice [43,44]. In particular, the development of newer, more potent nitrogen-containing BPs (N-BPs) has significantly improved treatment outcomes [45]. These compounds show a high binding affinity to hydroxyapatite and increased potency for inhibition of bone resorption [46–48]. They are administered as oral (alendronate and risedronate) or intravenous (zoledronate and neridronate) regimens. All intravenously administered N-BPs can induce an APR, which is characterized by fever, musculoskeletal pain, and other flu-like symptoms, and is treated with analgesics and antipyretics. Medical intervention may be required [49–52]. Although the cause of APR could be attributed to inflammation due to elevated levels of pro-inflammatory cytokines [53,54], interestingly, an observation in 90 postmenopausal women treated with N-BP for osteoporosis revealed: a negative association between circulating 25-hydroxyvitamin D (25(OH)D) levels and the development of APRs [55]. These results suggested that adequate administration of vitamin D preparations to vitamin D-deficient Paget's disease patients decreases the prevalence of common acute adverse events such as APRs following infusion of N-BPs [56]. Previously, less inflammatory VDR gene polymorphisms have also been investigated and may contribute to the reduction of APRs [57]. Adequate vitamin D status may contribute to obtaining a less inflammatory bone phenotype for bisphosphonates that act in PD.

**FIGURE 82.8** Model for 1,25(OH)<sub>2</sub>D<sub>3</sub> hyperresponsiveness of OCL precursors in PD. In this model, expression of the MVNP gene in pagetic OCL precursors increases IL-6, which in turn increases levels of TAF12. TAF12 forms transcription complexes with TAF4 and ATF7. The high levels of TAF12 permit the formation of VDR/TAF12/TAF4 transcription complexes at low levels of receptor occupancy by 1,25(OH)<sub>2</sub>D<sub>3</sub>. VDR-mediated transcription is then enhanced by ATF7. However, because ATF7 does not bind VDR directly; it is unclear if TAF12 is recruited to the CYP24A1 promoter by ATF7 or VDR. It is possible that VDR recruits TAF12 and the TAF12/TAF4–VDR complex and then brings in ATF7 to the VDRE to enhance VDR-mediated transcription. *MVNP*, measles virus nucleocapsid protein; *OCL*, osteoclast; *OCL-pre*, OCL precursors; *RXR*, retinoid receptor; *TBP*, TATA-binding protein; *VDR*, vitamin D nuclear receptor; *VDRE*, vitamin D response element.

## 8. Conclusions

The results presented in this chapter suggest that pagetic OCL precursors are hyperresponsive to 1,25(OH)<sub>2</sub>D<sub>3</sub> because of increased levels of TAF12, which acts as a VDR coactivator to enhanced VDR-mediated transcription. A model for the increased 1,25(OH)<sub>2</sub>D<sub>3</sub> responsivity in OCL in PD is shown in (Fig. 82.8). In this model, expression of the MVNP gene in pagetic OCL precursors increases IL-6, which in turn increases levels of TAF12. TAF12 forms transcription complexes with TAF4 and ATF7. The high levels of TAF12 permit the formation of VDR/TAF12/TAF4 transcription complexes at low levels of receptor occupancy by 1,25(OH)<sub>2</sub>D<sub>3</sub>. VDR-mediated transcription is then enhanced by ATF7. These results support the hypothesis that the pathophysiology underlying the increased OCL activity in PD is in part due to increased levels of VDR coactivators that enhance VDR-mediated transcription in OCL precursors and marrow stromal cells exposed to low levels of 1,25(OH)<sub>2</sub>D<sub>3</sub>, these results suggest that PD may represent in part an example of a VDR coactivator disease.

## 9. Summary points

- Osteoclast precursors from Paget's patients are hyperresponsive to 1,25(OH)<sub>2</sub>D<sub>3</sub> and express TAF12 that is TATA-Box binding protein-associated factor.
- TAF12 acts as a co-activator of VDR-mediated gene expression, by forming a complex with ATF7 and TAF4 that binds VDR via TAF12 and plays a key role in OCL formation stimulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> in both normals and Paget's patients.

- There is an increased occurrence of APRs to bisphosphonates in Paget's patients with low serum levels of 25OHD

# Vitamin D metabolism and disorders in companion animals

*Richard John Mellanby*

The Hospital for Small Animals, The Royal (Dick) School of Veterinary Studies, The University of Edinburgh, Edinburgh, United Kingdom

## CHAPTER OBJECTIVES

- To advance understanding in the role of vitamin D in skeletal and non-skeletal health in companion animals.
- To provide an overview of congenital and acquired disorders of vitamin D metabolism in companion animals.
- To highlight how vitamin D status can be diagnostically assessed in companion animals.

## 1. Introduction

Vitamin D plays an important role in regulating calcium metabolism and in the development and maintenance of skeletal health of veterinary species. In addition, and paralleling a similar phenomenon in human medicine, there is growing interest in understanding the role vitamin D has on nonskeletal health outcomes in companion animal species [1]. Here, we review vitamin D metabolism in dogs and cats and discuss both congenital and acquired vitamin D disorders. We conclude with an overview of our current understanding of the role vitamin D plays in the non-skeletal health of dogs and cats.

### 1.1 Metabolism and role of vitamin D on skeletal health

The importance of vitamin D on skeletal health has been known for almost a century [2]. In fact, the classic

experiments of Sir Edward Mellanby involved dogs, and through the supplementing of their restricted diet with either linseed or cod liver oil, he demonstrated that cod liver oil, but not linseed oil, could protect dogs from developing rickets [3]. The antirachitic factor in cod liver oil was later discovered to be vitamin D [2]. Although unknown to Sir Edward Mellanby at the time, the heavy reliance of dogs on dietary sources of vitamin D and their failure to produce vitamin D cutaneously meant that their vitamin D-depleted diet was highly effective at inducing rickets in his experimental population.

Veterinary species vary widely in their ability to produce vitamin D cutaneously. Dogs and cats, unlike many other mammals, cannot produce vitamin D cutaneously so are reliant on their diet to obtain vitamin D [4–7]. In contrast, sheep, cattle, and pigs are able to produce vitamin D cutaneously. Both experimental and observational studies in countries where UVB exposure seasonally varies provide clear evidence of the importance of cutaneously derived vitamin D in dogs [7,8]. Dogs and cats are unable to cutaneously produce vitamin D due to the high activity of 7-dehydrocholesterol reductase enzyme that converts 7-dehydrocholesterol into cholesterol. In vitro studies have revealed that total 7-dehydrocholesterol concentrations in the skin of dogs and cats were markedly lower than rats. After sun exposure, there was no change in vitamin D<sub>3</sub> concentrations in dog and cat skin extracts, while there was a 40-fold increase in vitamin D<sub>3</sub> concentrations in rat skin [5]. In cats, an in vivo study demonstrated that the vitamin D status of kittens increases following treatment with a 7-dehydrocholesterol reductase enzyme inhibitor when exposed to ultraviolet light [9]. It is unclear why cats and dogs have a striking failure to cutaneously generate

vitamin D in contrast to almost all other mammals, which have been studied to date; it is widely speculated that their inability to synthesize vitamin D in the skin is related to the consumption of prey containing significant amounts of vitamin D, notably in their liver and adipose tissue, which means there is no physiological requirement for the skin to produce vitamin D [10].

Dietary vitamin D is available in two forms, namely vitamin D<sub>2</sub> (ergocalciferol) and D<sub>3</sub> (cholecalciferol), with most pet foods supplemented with vitamin D<sub>3</sub> (cholecalciferol) [11]. Following intestinal absorption, vitamin D<sub>2</sub> and D<sub>3</sub> enter the circulation and are predominately bound to the vitamin D-binding protein (DBP), with a small percentage also bound to albumin; [12,13] other vitamin D metabolites are also bound in this manner. Less than 1% of vitamin D circulates as free (unbound) and is readily available for cellular utilization [14,15]. It is possible that vitamin D that is bound to the DBP can also exert a biological effect as several target organs of 25(OH)D express megalin, a transmembrane protein that mediates internalization of DBP-bound metabolites. Vitamin D<sub>2/3</sub> are pro-hormones that are subsequently activated by sequential hydroxylation steps by the action of cytochrome P450 (CYP) enzyme family [16]. Vitamin D is first hydroxylated at C25 in the liver to 25-hydroxyvitamin D (25(OH)D), primarily catalyzed by 25-hydroxylases CYP2R1 in the endoplasmic reticulum of the liver and to a lesser extent by CYP27A1 in the liver mitochondria [17,18]. Hydroxylation at C1 $\alpha$  in the proximal tubule of the kidney converts 25(OH)D to the most hormonally active form, 1 $\alpha$ ,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) (calcitriol). Hydroxylation at C1 $\alpha$  occurs in the kidney mitochondria by the action of 1 $\alpha$ -hydroxylase CYP27B1 [19] (see Chapter 4). This enzyme has been detected in other tissues and cell types, and evidence of local production of 1,25(OH)<sub>2</sub>D was a major contributor to identifying extraskeletal roles of vitamin D [20–22] (see Chapter 9). The regulation of CYP27B1 is tightly controlled via parathyroid hormone (PTH) [23–25] and fibroblast growth factor 23 (FGF23) [26], as well as a negative feedback loop whereby 1,25(OH)<sub>2</sub>D acts on itself to suppress CYP27B1 and induce its own catabolism by promoting CYP24A1 [24,27] (see Chapter 8). CYP24A1 can induce C23 and C24 hydroxylation of 1,25(OH)<sub>2</sub>D and 25(OH)D [16,28,29]. C24 hydroxylation of 1,25(OH)<sub>2</sub>D results in a five-step process, which culminates with calcitroic acid being excreted in the bile [30]. C24 hydroxylation of 25(OH)D<sub>3</sub> forms 24,25-dihydroxyvitamin-D<sub>3</sub> (24,25(OH)<sub>2</sub>D<sub>3</sub>). 24,25(OH)<sub>2</sub>D<sub>3</sub> was thought to be an inactive catabolic product of 25(OH)D<sub>3</sub>; however, studies have now shown that it exerts biological activity independent of the vitamin D receptor (VDR) [31–34] (see Chapter 5).

Vitamin D metabolites can also be metabolized via the C3-epimerization pathway. C3-epimerization results in the hydroxyl group at position C3 of the

A-ring of the vitamin D metabolite structure being converted from the alpha to beta orientation, forming stereoisomers of the original metabolite (the only difference between the molecules is the spatial arrangement of the hydroxyl group at C3). All major vitamin D intermediate metabolites are susceptible to epimerization in this way; the process is irreversible and is independent on the presence of a hydroxyl group at the C1 $\alpha$  and C25 positions; [35] and epimers can be further metabolized by hydroxylases at C1 $\alpha$  and C25 as in the standard pathway [36–38]. This means that, not only can 25(OH)D, 1,25(OH)<sub>2</sub>D, and 24,25(OH)<sub>2</sub>D all be epimerized to 3-epi-25(OH)D, 3-epi-1,25(OH)<sub>2</sub>D, and 3-epi-24,25(OH)<sub>2</sub>D, respectively, but 3-epi-25(OH)D can be C1 $\alpha$  and C24 hydroxylated by their respective CYP enzymes [37–40]. The enzyme responsible for C3-epimerization has yet to be identified, but the process can occur in a range of extrarenal tissues and cell types, and it employs enzymes distinct from those classically involved in vitamin D metabolism [41–43] (see Chapter 6).

The principal role of 1,25(OH)<sub>2</sub>D, acting alongside PTH and calcitonin, is to maintain circulating calcium concentrations within a tight reference range [1,44]. 1,25(OH)<sub>2</sub>D exerts its actions on target cells and tissues following binding to the VDR, which is widely expressed in most canine tissues [45]. The VDR-1,25(OH)<sub>2</sub>D complex then heterodimerizes with the retinoic acid receptor, retinoid X receptor (RXR). This complex exerts genomic actions as a transcription factor to regulate target genes that contain a vitamin D response element in their promoter, which then influence numerous physiological processes [2] (Chapters 10–13). Alternatively, 1,25(OH)<sub>2</sub>D can bind to the plasma membrane VDR to induce rapid response biological actions, for example, the stimulation of intestinal calcium transport, which are non-genomic actions of 1,25(OH)<sub>2</sub>D [46,47]. Calcium homeostasis is achieved mainly by the ability of 1,25(OH)<sub>2</sub>D to increase intestinal absorption of calcium [46]. 1,25(OH)<sub>2</sub>D can also increase calcium reabsorption in the distal renal tubule and mobilizes the release of calcium from the skeleton in conjunction with PTH during periods of hypocalcemia [48]. When circulating concentrations of calcium decline, increased plasma PTH concentrations lead to an increase in renal CYP27B1 activity, which in turn raises circulating 1,25(OH)<sub>2</sub>D concentrations. The epimeric forms of 1,25(OH)<sub>2</sub>D also appear to have a role in calcium homeostasis. For example, 3-epi-1,25(OH)<sub>2</sub>D<sub>3</sub>, the most biologically active epimer, can suppress PTH secretion to a similar degree as the parent metabolite [35,37,46]. Despite this, 3-epi-1,25(OH)<sub>2</sub>D<sub>3</sub> has low calcemic effects [39,49] and anti-proliferative activity of ~30% of that of the non-epimeric form; [37,38] it also exhibits reduced affinity for binding to the DBP and the

VDR [38,40,41,50,51]. This reduced affinity results in reduced ability to induce calcium transport [52].

## 1.2 Measurement of vitamin D metabolites in veterinary species

Although a wide range of vitamin D metabolites can be measured using a variety of instrumentation and technologies, the primary vitamin D metabolites measured in both human and veterinary clinical cases are 25(OH)D and 1,25(OH)<sub>2</sub>D [53]. 25(OH)D has a half-life of 2–3 weeks and is widely regarded as the most accurate measurement to assess vitamin D status [54]. 25(OH)D serves as a reservoir for the generation of the more biologically active 1,25(OH)<sub>2</sub>D. 25(OH)D can be measured by a wide range of assays including chemiluminescent immunoassay, enzyme immunoassay, radioimmunoassay, high-performance liquid chromatography (HPLC), and the widely considered gold standard technique of liquid chromatography tandem mass spectrometry (LC-MS/MS) [55,56] (see Chapters 48–50).

The accurate quantification of vitamin D metabolites, even of 25(OH)D, can be challenging. The vitamin D pathway is a highly complex and dynamic system involving a number of structurally very similar compounds, which may interfere with analysis; not only that but also the metabolites circulate predominantly bound the DBP and at low concentrations, meaning they are particularly challenging to identify, isolate, and accurately quantify (see Chapter 49).

Immunoassay-based techniques can be integrated into fully automated laboratory systems allowing for rapid analysis in a high-throughput clinical chemistry laboratory setting. They offer good sensitivity for 25(OH)D and require minimal sample volume; however, selectivity continues to be one of their major limitations [57–59]. Cross-reactivity with different vitamin D metabolites, especially 24,25(OH)<sub>2</sub>D, occurs in many of the immuno-based assays. Lack of selectivity between 25(OH)D<sub>2</sub> and 25(OH)D<sub>3</sub>, and unequal cross-reactivity of the two metabolites can cause bias and have a significant impact depending on the sample being analyzed. Furthermore, vitamin D metabolites must be released from the DBP to be measured, which is difficult to achieve in automated immunoassays in which strong organic solvents cannot be used [57,58]. Therefore, samples in which variation in the DBP levels exists (during pregnancy or cases of renal disease, for example) are known to impact on the performance of these assays.

LC-MS/MS is considered the gold standard method for analyzing vitamin D metabolites in veterinary patients [60–62]. This method does not suffer from those limitations outlined before for immunoassays and has

the capability to detect and quantify multiple, highly similar analytes simultaneously within one sample, enabling the profiling of several metabolites of the vitamin D pathway. Using LC-MS/MS facilitates the effective release of vitamin D metabolites from the DBP during sample preparation by the use of strong organic solvents. High levels of selectivity are achieved in LC-MS/MS methods by the chromatographic resolution of individual analytes and detection based on specific mass-to-charge (*m/z*) ratios and fragmentation patterns, meaning that D<sub>3</sub> and D<sub>2</sub> metabolites can be distinguished and quantified individually.

Isomeric and isobaric metabolites such as the C3-epimers complicate the bioanalytical assessment of vitamin D metabolites even by LC-MS/MS. The C3-epimers have the same molecular mass as the non-epimer metabolites, meaning they are not distinguished in the mass spectrometer and many LC-MS/MS assays do not separate them. However, optimization of the LC parameters and the use of specialist LC columns can ensure that sufficient resolving power can be achieved and the C3-epimers can be chromatographically separated for accurate quantitation. Although low levels of 3-epi-25(OH)D have been recently detected in dogs [63], cats have much higher concentrations [64], which, given the unconfirmed biological activity of the C3-epimers, if not resolved from 25(OH)D may overestimate 25(OH)D concentration.

As LC-MS/MS has the capability to assess multiple metabolites from a single sample, assays that include the measurement of other vitamin D metabolites are now being reported. Since 1,25(OH)<sub>2</sub>D has the most impact on calcium homeostasis, there are clinical indications for its measurement, notably in dogs with hypercalcemia caused by calcitriol exposure. A range of assays have been reported for the quantification of 1,25(OH)<sub>2</sub>D, including immunoassays and LC-MS/MS methodologies [56]. Serum concentrations of 24,25-dihydroxyvitamin D, the degradation product of 25(OH)D, have been quantified in dogs and found to be present in higher concentrations than other species [65]. 24,25-Dihydroxyvitamin D can only be measured by LC-MS/MS, which also provides concomitant quantification of 25(OH)D, thus allowing calculation of the 25(OH)D: 24,25-dihydroxyvitamin D ratio, also known as the vitamin D metabolite ratio (VMR).

Free 25(OH)D concentrations have recently been quantified in dogs for the first time using an enzyme-linked immunosorbent assay (ELISA). In 117 healthy dogs, the median and interquartile range of free 25(OH)D concentrations detected was 15.2 (12.5–23.2) pmol/L [63]. Further studies are required to ascertain whether total or free 25(OH)D concentration is the best assessment of vitamin D status in companion animals. This is likely to have important clinical implications.

For example, in people, DBP levels change significantly during pregnancy influencing the concentration of vitamin D metabolites including 25(OH)D [66] highlighting the merits of measuring free 25(OH)D [67].

One of the main challenges regarding vitamin D analysis in veterinary samples is the lack of standardization between laboratories [68]. Harmonization of 25(OH)D testing has been historically challenging but has improved recently through the development of standard reference materials (SRMs) for some metabolites [69] and reference method procedures (RMPs) [70–72] by the Vitamin D Standardization Program (VDSP) and External Quality Assessments (EQAs) such as the Vitamin D External Quality Assessment Scheme (DEQAS). DEQAS, a global quality assurance scheme for laboratories measuring vitamin D metabolites [73], enables participating laboratories to validate and continuously monitor their assay performance in comparison with both National Institute of Standards and Technology (NIST) RMPs and other laboratories using the same method. These programs have considerably reduced the variability between laboratories [68,74]. SRMs will be required for other vitamin D metabolites, and there are currently no EQAs specific for the assessment of vitamin D in veterinary samples (DEQAS assesses the analysis of vitamin D metabolites in human serum samples). This aspect of vitamin D quantification is discussed in greater detail in Chapter 49.

## 2. Dog

### 2.1 Congenital vitamin D disorders

Congenital disorders of vitamin D homeostasis are well described in dogs although they are rarely observed in clinical practice. Similar to the approach taken in classifying human vitamin D metabolism disorders, genetic vitamin D disorders in animals are typically subdivided into three main types [75]. Vitamin D–dependent rickets type 1A (VDDR-1A) refers to animals with CYP27B1 deficiencies, which leads to impaired conversion of 25(OH)D to the most metabolically active vitamin D metabolite 1,25(OH)<sub>2</sub>D [76]. In contrast, vitamin D–dependent rickets type 1B is caused by mutations in CYP2R1 gene, leading to failure of vitamin D to be converted to 25(OH)D [77]. Both type 1A and 1B are inherited as autosomal recessive traits [76]. The main consequences of these disorders are hypocalcemia, which can be severe enough to cause seizures and skeletal abnormalities; generalized skeletal pain can also be a feature [75]. The third group of genetic vitamin D disorders is vitamin D–dependent rickets type 2A (VDDR-2A), also called hereditary vitamin D–resistant rickets (HVDRR), which involves mutations in the VDR gene. In this rare

condition, hypocalcemia, secondary hyperparathyroidism, and increased concentration of 1,25(OH)<sub>2</sub>D are typical biochemical changes alongside skeletal changes and accompanying pain, which is consistent with rickets [78]. Alopecia may also be a feature of VDR gene mutations. Treatment is challenging and based around high-dose calcium and 1,25(OH)<sub>2</sub>D supplementation. VDDR-2A has been reported in a Pomeranian dog [78].

Provisional diagnosis of these congenital vitamin D disorders is usually based on compatible clinical signs in young patients, who have a dietary history, which demonstrates adequate vitamin D intake. Definitive diagnosis can be more challenging although a genetic test for VDDR-2A is available for Pomeranian dogs (Laboklin, UK).

### 2.2 Acquired vitamin D disorders—deficiency

Acquired vitamin D disorders can result from either an excess or deficiency of vitamin D. An important cause of vitamin D deficiency in companion animals is the consumption of a diet, which is deficient in vitamin D. The European pet food industry (FEDIAF) nutritional guidelines state that the minimum recommended vitamin D allowance for adult dogs is 55.2 IU and for adult cats 25 IU per 100g dry matter. One study demonstrated that 25(OH)D concentration was highly variable, including some instances of hypovitaminosis D, in healthy dogs fed a variety of different commercial diets, possibly implying that some commercial diets might contain inadequate quantities of vitamin D [79]. However, a recent study demonstrated that the majority of proprietary dog foods tested contained vitamin D concentrations within the manufacturers' stated range [80]. Consequently, most cases of hypovitaminosis D occur in dogs and cats fed improperly prepared homemade diets [79,81–84]. The hypovitaminosis D state may result in hypocalcemia, secondary hyperparathyroidism, and possible skeletal abnormalities, typically rickets in young animals and osteomalacia in older dogs [85]. In rickets, the classical skeletal changes include impaired mineralization of physeal and epiphyseal cartilage with lesions typically involving the fastest growing bones such as the radius, tibia, metacarpals, and metatarsals. Clinically, this manifests as a stiff, lame gait, deformed limbs, pain on palpation of bones, and muscle weakness. Seizures may also occur due to hypocalcemia [75]. On radiographic and postmortem examination, typical changes include widening of the physeal growth plate, metaphyseal flaring, poor skeletal mineralization, and potentially pathological fractures [75].

Low vitamin D status has been reported in dogs with gastrointestinal disorders, especially in dogs with a

protein losing enteropathy (PLE) [86,87], as well as dogs with exocrine pancreatic insufficiency [88], acute pancreatitis [89], and liver disease [90].

### 2.3 Acquired vitamin D disorders—excess

Vitamin D excess and associated hypercalcemia can occur in dogs through the consumption of diets containing disproportionately high concentrations of vitamin D. This typically occurs as a consequence of inadvertent consumption of vitamin D containing rodenticides or medications, or through the administration of inappropriately vitamin D-enriched commercial diets [91–94]. As with vitamin D minimum values, the (FEDIAF) nutritional guidelines also state the safe maximum values and European legal limit of vitamin D that canine commercial diets should contain is 320 IU/100g DM (EU legal limit 227 IU/100g DM). Homemade and commercial raw diets have been shown to contain vitamin D concentrations above the recommended maximum [95]. Although dogs can tolerate oral vitamin D doses above the recommended allowance of 55.2 IU/100g DM without major ill effect [96], significant overfortification of foodstuff with vitamin D can lead to debilitating hypercalcemia [97].

Hypervitaminosis D secondary to rodenticide consumption is well recognized and, unfortunately, is likely to be an increasing problem as some rodenticide manufacturers switch to vitamin D-containing products [93,98]. Consumption of vitamin D-containing medication is also an increasingly well-recognized cause of hypervitaminosis D in companion animals. This can arise due to the ingestion of oral vitamin D supplements or unintentional consumption of ointments containing vitamin D analogs, now widely prescribed for psoriasis treatment [99–101]. There have been reported cases of dogs developing hypervitaminosis D as a consequence of licking owner's skin covered in topical ointments containing 1,25(OH)<sub>2</sub>D or vitamin D analogs or through consumption of detached 1,25(OH)<sub>2</sub>D-containing skin plaques [102,103].

Clinical disease occurs in hypervitaminosis D states when vitamin D metabolite concentrations become sufficiently increased to cause hypercalcemia, resulting in clinical signs such as polydipsia, polyuria, lethargy, and inappetence. Acute renal failure and long-term complications caused by widespread soft-tissue mineralization can occur in the most severely affected individuals [93]. Two dogs diagnosed with hypervitaminosis D had serum 25(OH)D concentrations around 400 nmol/L (reference range 17–140 nmol/L) when measured in DEQAS accredited laboratory [104]. Where there is known exposure to potentially toxic doses of vitamin D, immediate treatment involves induction of emesis

followed by administration of activated charcoal, in conjunction with supportive and symptomatic care, typically involving intravenous fluid therapy [93]. Intravenous lipid emulsion has been recently reported as a method to successfully lower serum 25(OH)D concentrations in a dog with vitamin D toxicity [105]. Both experimentally and clinically, bisphosphonates have been successfully used to treat hypervitaminosis D, with intravenous pamidronate or zoledronate the most widely utilized [54,106]. While bisphosphonates are effective and generally well tolerated in dogs [107], complications such as osteonecrosis are increasingly well recognized [108,109]. The lipid-soluble properties of vitamin D can lead to sequestration of the vitamin into fat deposits in the body. Consequently, it can take several months for the serum 25(OH)D concentrations to return to within the reference interval following a hypervitaminosis D episode [98].

Endogenous overproduction of active vitamin D metabolites is another mechanism for the development of hypervitaminosis D. This classically occurs in patients with granulomatous diseases where a dysregulated immune response results in the excessive production of 1,25(OH)<sub>2</sub>D from 25(OH)D, typically by macrophages, without the regulation of negative feedback. This syndrome has been reported in dogs with sterile granulomatous lymphadenitis [110], granulomatous inflammation following placement of a biological implant [111], *Angiostrongylus vasorum* infections [112] and *Mycobacterium avium* subspecies *hominissuis* infection [113]. Excessive production of 1,25(OH)<sub>2</sub>D has also been postulated to be important in driving hypercalcemia in dogs with autoimmune diseases such as immune-mediated polyarthritis [114]. Successful treatment of the underlying condition typically resolves the increases in systemic 1,25(OH)<sub>2</sub>D concentrations and associated hypercalcemic state [114].

### 2.4 Role of vitamin D on non-skeletal health in dogs

The vital role of vitamin D in the maintenance of bone health and calcium homeostasis has been widely acknowledged since the discovery of vitamin D nearly a century ago. Since the more recent discovery of VDR expression in tissues beyond the intestines, kidney, and bone, many studies have investigated the non-skeletal health benefits of vitamin D in both humans and dogs [1,115].

#### 2.4.1 Gastrointestinal diseases

In dogs with PLE, total hypocalcemia is not an uncommon biochemical abnormality, and historically, this has been attributed to a reduction in protein-

bound calcium, secondary to hypoalbuminemia [116,117]. However, the wider availability of ionized calcium assays has generated a greater awareness that many dogs with a PLE have reductions in ionized as well as protein-bound calcium [118]. While a blunted PTH response due to concurrent hypomagnesemia has been postulated to be an important driver of hypocalcemia in some cases of PLE [119], there is a growing consensus that low concentrations of 25(OH)D play an important role in the development of the hypocalcemic state associated with PLE in dogs [86,120]. A positive correlation was identified between 25(OH)D concentrations, serum albumin, and ionized calcium levels in dogs with inflammatory bowel disease (IBD) in one study [86]. This study also demonstrated that dogs with PLE had markedly lower 25(OH)D concentrations compared with a healthy control population, dogs with intestinal inflammation who were normoalbuminemic and hospitalized dogs without gastrointestinal signs. Furthermore, serum 25(OH)D concentration has been found to be negatively correlated with duodenal histopathology scores [121] and inversely correlated with canine IBD activity index [86]. Similarly, dogs with a chronic inflammatory enteropathy (CIE) and low serum 25(OH)D concentrations had higher canine chronic enteropathy clinical activity index scores compared with CIE dogs with normal serum 25(OH)D concentrations [121]. In some dogs with a PLE, the hypovitaminosis D and secondary hypocalcemia can be so severe that neurological signs, including seizures, can be a significant clinical complication of the intestinal disease [122,123]. Additionally, the severity of the hypovitaminosis D state has been shown to correlate with adverse clinical outcomes in dogs with a PLE [120,124].

The cause of hypovitaminosis D in PLE is likely to be multifactorial. Malabsorption of fat-soluble vitamin D (especially in dogs with lymphangiectasia) is widely considered to be the most important cause; however, if this was the sole etiology, malabsorption of other fat-soluble vitamins, such as vitamin K, might be expected to occur simultaneously [119]. Although this has not been specifically investigated, significant vitamin K deficiency would be a rare complication of PLE given the absence of coagulopathies caused by a deficiency in vitamin K-dependent clotting factor although dogs with PLE have been described as hypercoagulable [125].

Other factors that may contribute to the depletion of vitamin D in PLE patients include ongoing systemic inflammation, reduced dietary intake of vitamin D, and increased vitamin D metabolism. Additionally, 1,25(OH)<sub>2</sub>D has immunomodulatory effects, which may support mucosal health [126]. Due to this immunomodulatory role, it is also possible that patients with PLE develop this disease in part due to their 25(OH)D deficiency [67]. A human study demonstrated that

women who had low 25(OH)D levels were at an increased risk of the development of Crohn's disease [67]. Finally, magnesium is required for the hydroxylation step necessary to produce 1,25(OH)<sub>2</sub>D in the renal tubules. Therefore, concurrent hypomagnesemia in dogs with PLE may consequently reduce the amount of 1,25(OH)<sub>2</sub>D available [119]. Protocols for correction of hypovitaminosis D associated with chronic enteropathy have not been well established in human or veterinary medicine. Although parenteral administration of calcitriol would be logical, due to the concerns about impaired gastrointestinal absorption of fat-soluble vitamins, in people with IBD, enteral supplementation is often utilized and is beneficial [127]. The optimal dose of calcitriol and the duration of treatment are also uncertain [86].

#### **2.4.2 Pancreatic and hepatic diseases**

Dogs with pancreatic and hepatic disorders have also presented with low serum concentrations of 25(OH)D. Dogs with weight loss and exocrine pancreatic insufficiency (EPI) were found to have significantly lower serum 25(OH)D concentrations than dogs with EPI and stable weight [88]. Additionally, concentrations of three fat-soluble vitamins (A, E, and D) remained reduced in dogs with EPI even after pancreatic enzyme supplementation [88]. The reason for this is uncertain, hypothesized explanations include; long-term dietary fat malabsorption, which is refractory to pancreatic enzymes supplementation, depletion of stored vitamin D due to the loss of adipose tissue associated with weight loss, or ongoing reduced dietary intake secondary to the EPI. Dogs with acute pancreatitis had lower 25(OH)D status than healthy dogs [89]. In addition, dogs with acute pancreatitis that survived had significantly higher serum 25(OH)D concentrations than dogs who died [89]. This positive correlation between reduced vitamin D status and prognosis has also been identified in human studies [128,129]. Vitamin D deficiency and rickets has occasionally been reported in dogs with liver diseases likely as a consequence of impaired intestinal absorption of vitamin D [90]. Vitamin D status has been negatively linked to disease severity in dogs with liver disorders [130]. Serum concentrations of 25(OH)D increased following the surgical correction of a congenital extrahepatic portosystemic shunt [131].

#### **2.4.3 Infectious diseases**

Vitamin D status has been found to be lower in patients with a wide variety of infectious diseases. Dogs with clinically active leishmaniasis [132], blastomycosis [133], babesiosis [134], and *Spirocerca lupi* [135] infections had lower 25(OH)D status than healthy dogs. Similarly, cats with mycobacteria and feline immunodeficiency virus infections had lower 25(OH)D concentrations than

healthy cats [136,137]. A negative relationship between 25(OH)D concentrations and disease severity has also been reported in dogs with babesiosis and *S. lupi* infections [134,135]. Serum concentrations of 25(OH)D have been found to decline in dogs, which developed clinical leishmaniasis [138]. Vitamin D status was also lower in shelter dogs with infectious respiratory disease complex compared with healthy shelter dogs [139].

#### **2.4.4 Immune-mediated diseases**

The role of vitamin D in immune-mediated and inflammatory diseases was explored, in part, due to the identification of the VDR on the surface of many cell types, including leukocytes [140]. Consequently, dogs with a range of immune-mediated diseases, including immune-mediated hemolytic anemia, thrombocytopenia, and polyarthritis, have been found to have altered vitamin D homeostasis [141] and reduced concentrations of 25(OH)D. Additionally, low serum 25(OH)D concentrations were also predictive of a poorer clinical outcome in dogs with immune-mediated diseases [141]. Dogs with acute polyradiculoneuritis had lower circulating 25(OH)D concentrations than dogs with idiopathic epilepsy [142]. Interest in the relationship between autoimmune diseases and vitamin D has been fueled by the growing evidence that vitamin D metabolites can influence the canine immune cell function and phenotype *ex vivo*, typically switching innate immune cells from a pro-inflammatory to a more anti-inflammatory response [143,144]. For example, a recent *in vitro* study using blood from healthy shelter dogs identified that the concentrations of tumour necrosis factor- $\alpha$  significantly decreased, while interleukin-10 significantly increased, following incubation with 1,25(OH) $_2$ D [145].

#### **2.4.5 Endocrine diseases**

Dogs with naturally occurring hypercortisolism have been found to have 25(OH)D concentrations lower than healthy dogs [146]. The cause of this decrease is incompletely understood but may be related to increased urinary loss of vitamin D metabolites or due to increased degradation of 25(OH)D.

#### **2.4.6 Cardiovascular diseases**

Circulating 25(OH)D concentrations were significantly lower in dogs with congestive heart failure compared with unaffected dogs even though the two groups had a similar dietary vitamin D intake [147]. 25(OH)D concentrations were also found to be lower in dogs with chronic valvular disease stage B2 and C/D disease than dogs with stage B1 disease [148].

#### **2.4.7 Oncology**

The connection between vitamin D status and neoplasia has been extensively investigated in human medicine, with one study finding that serum 25(OH)D concentrations greater than 40 ng/mL resulted in a reduced risk of rectal, colonic, and breast cancer [149]. Several studies have shown that vitamin D metabolites have anti-proliferative effects on canine cancer cell lines *in vitro* [150–152]. Vitamin D status of dogs with cancer has frequently been reported to be lower than control populations. For example, dogs with mast cell tumors had lower 25(OH)D concentrations than healthy dogs despite having no significant differences in vitamin D oral consumption [153]. Dogs with three different types of cancer (mast cell tumor, lymphoma, and osteosarcoma) all had altered vitamin D metabolism compared with the healthy control population [154]. Another study found that relative risk of cancer in dogs increased with decreasing 25(OH)D concentrations [155]. Dogs with B cell lymphoma were found to have lower plasma concentrations of 25(OH)D than healthy dogs [154]. However, other studies have failed to find a difference in vitamin D homeostasis in dogs with and without cancer including the observation that 25(OH)D concentrations were not significantly different between dogs with an osteosarcoma and control dogs [156].

#### **2.4.8 Urinary tract disease**

In dogs with chronic kidney disease (CKD), lower levels of serum 25(OH)D have been identified [157,158]. In addition, low concentrations of 1,25(OH) $_2$ D have also been reported in dogs with CKD. This is thought to be due to a combination of lower availability of 25(OH)D, reduced CYP27B1 (1 $\alpha$ -hydroxylase) activity due to renal damage, and urinary loss of vitamin D [158,159]. The decline in 1,25(OH) $_2$ D concentration is considered important in the development of secondary hyperparathyroidism in CKD, leading to interest in the potential therapeutic merits of 1,25(OH) $_2$ D supplementation in companion animals with renal failure [159,160]. One unpublished study found that judicious administration of 1,25(OH) $_2$ D may confer a survival benefit in dogs with IRIS stage 3 and 4 providing calcium, phosphate, and PTH can be closely monitored [161]. A recent study found that administering an extended release form of 25(OH)D to dogs with CKD resulted in an increase in vitamin D metabolites, including 1,25(OH) $_2$ D, while avoiding hypercalcemia [162]. However, the benefits of long-term 25(OH)D supplementation on the progression of CKD, and the patient's quality of life, remained undetermined in this study [162].

Vitamin D homeostasis disorders may increase the risk of other renal disorders, with a recent study suggesting that altered vitamin D catabolism may predispose some dogs to the development of calcium oxalate uroliths [163]. In dogs with non-azotemic protein losing nephropathy (PLN), a significant positive correlation between serum albumin and concentrations of both 25(OH)D and 24,25(OH)<sub>2</sub>D was observed [164]. Additionally, dogs with PLN had significantly lower serum 25(OH)D, 1,25(OH)<sub>2</sub>D, and 24,25(OH)<sub>2</sub>D concentrations compared with the control population [164].

#### 2.4.9 Inflammation

Several studies have shown an inverse relationship between biomarkers of inflammation and vitamin D status in dogs. For example, serum 25(OH)D concentrations in dogs diagnosed with a CE have been shown to negatively correlate with circulating neutrophil, monocyte, and serum pro-inflammatory cytokines [165]. Furthermore, two studies have observed that vitamin D status in dogs with a CE negatively correlated with severity of intestinal inflammation [121,165]. Dogs with blastomycosis also had a negative relationship between vitamin D status and neutrophil counts [133], and CRP was significantly lower in a population of healthy dogs with a serum 25(OH)D concentration above 100 ng/mL compared with dogs with a 25(OH)D concentration below 100 ng/mL [155]. However, the widely reported negative association between vitamin D status and inflammation is not an absolute consensus, with one study reporting an increase in both C-reactive protein and 25(OH)D concentrations in racing sled dogs [65].

#### 2.4.10 Dermatology

Serum 25(OH)D concentrations in dogs with atopic dermatitis were not significantly different from healthy dogs [166]. However, atopic dogs that responded well to prednisolone had higher serum 25(OH)D concentrations [166]. Oral vitamin D treatment has been shown to improve clinical outcomes in an atopic dermatitis treatment trial with an increase in serum 25(OH)D correlating to a reduction in pruritus and skin lesions [167]. In this study, paricalcitol, a VDR agonist, was also trialed in a small number of dogs; however, unacceptable side effects including hypercalcemia and polyuria/polydipsia resulted in withdrawal of treatment [167].

#### 2.4.11 Critical care

Several studies have identified a relationship between low vitamin D status and adverse clinical outcomes in hospitalized dogs. Vitamin D status in critically ill dogs that survived was found to be significantly higher than in dogs that died [168]. Critically ill dogs and dogs with sepsis had significantly lower serum 25(OH)D

concentrations compared with healthy control dogs, and 25(OH)D concentration was an independent predictor of in-hospital and 30-day survival [169]. Experimental induction of inflammation is known to reduce 25(OH)D concentrations in dogs [170].

### 3. Cat

Feline VDDR-1A has been reported [76,171], while type 1B has been reported in a cat [77]. The disorders can be managed, with varying degrees of success, mainly through 1,25(OH)<sub>2</sub>D supplementation. VDDR-2A has been reported in the veterinary literature in cats [172–174]. Experimentally, the dysfunction of the vitamin D receptor in VDDR-2A has been proven by the inability of skin fibroblasts, which express VDR, to effectively bind 1,25(OH)<sub>2</sub>D [172,174]. Additionally, entire DNA sequencing of the feline CYP27B1 gene has also been described as a means of diagnosing VDDR-1A [77]. Low vitamin D status has been reported in cats with gastrointestinal disorders (compared with healthy controls) [175].

Vitamin D excess and associated hypercalcemia can occur in dogs through the consumption of diets containing disproportionately high concentrations of vitamin D. This typically occurs as a consequence of inadvertent consumption of vitamin D containing rodenticides or medications, or through the administration of inappropriately vitamin D-enriched commercial diets [91,93,176,177]. Historically, increased concentrations of vitamin D have been observed in some cat foods, which has been attributed to their high content of oily fish [176,177]. In cases of hypervitaminosis D, acute renal failure and long-term complications caused by widespread soft-tissue mineralization can occur in the most severely affected individuals [93,176,177]. As with vitamin D minimum values, the FEDIAF nutritional guidelines also state the safe maximum values and European legal limit of vitamin D that canine and feline commercial diets should contain: for cats, a maximum of 3000 IU/100 g DM is safe for all feline life stages (EU legal limit 227 IU/100g DM).

#### 3.1 Role of vitamin D on non-skeletal health in cats

Low vitamin D status has been observed in numerous feline infectious diseases including blastomycosis [178], *Mycobacterium* infection [179], feline infectious peritonitis [180], Toxoplasmosis [180], *Nocardia* infection [181], Cryptococcosis [180], feline immunodeficiency virus [137], and rhinitis caused by *Actinomyces* [180].

In addition, many cats with cholestatic liver disease, especially hepatic lipidosis, have been reported to have low serum 25(OH)D levels [182]. In cats, both 25(OH)D and a C-3 epimer of 25(OH)D were lower in cats with cardiomyopathy compared with healthy cats, although, when patient age was taken into account, this did not reach statistical significance since older cats had significantly lower 25(OH)D concentrations [183]. Hospitalized cats with neutrophil counts above the reference range had lower serum 25(OH)D concentrations than cats with neutrophil counts below the upper limit of the reference range [184].

A study of hospitalized cats found that cats, which died within 30 days of initial assessment, had significantly lower 25(OH)D than cats that survived [185]. Further analysis revealed that the relationship between vitamin D status and mortality risk was not linear, as cats within the lowest 25(OH)D tertile had a significantly higher mortality risk than cats in the upper or middle tertile [185]. Low vitamin D status has also been associated with anemia in hospitalized cats [186].

The decline in 1,25(OH)<sub>2</sub>D concentration is considered important in the development of secondary hyperparathyroidism in CKD, leading to interest in the potential therapeutic merits of 1,25(OH)<sub>2</sub>D supplementation in companion animals with renal failure [159,160,187].

#### 4. Conclusions and future directions

While numerous studies have linked low vitamin D status to adverse non-skeletal health outcomes in cats and dogs, there is still significant uncertainty over the importance of vitamin D in shaping clinical outcomes in non-skeletal disorders. The optimal way to supplement vitamin D also remains uncertain, in terms of both the route of administration (enteral vs. parenteral) and the vitamin D metabolite of choice (25(OH)D, 1,25(OH)<sub>2</sub>D or cholecalciferol). The relationship between low 25(OH)D concentrations and the development or outcomes of non-skeletal disorders cannot be considered to be invariably causative and may, in fact, be due to reverse causation. For example, serial measurements of circulating 25(OH)D concentrations in experimental and human patients have shown that inflammation and infections can result in lower vitamin D status [188–190]. A recent study that longitudinally tracked both markers of inflammation and 25(OH)D concentrations in dogs undergoing elective surgery have recently shown that the postoperative increase in acute phase proteins is mirrored by modest declines in total, but not free, serum 25(OH)D concentrations [191]. To disentangle the relationship between vitamin D and non-

skeletal health outcomes, human-focused studies have embraced Mendelian randomization approaches as well as examining the non-skeletal health benefits of long-term vitamin D supplementation in large-scale clinical trials [192,193]. Mendelian randomization techniques use genetic variation as a natural experiment to investigate the causal relations between potentially modifiable risk factors and health outcomes in observational data [193]. This approach has allowed the health consequences of genetically determined low lifetime vitamin D status to be studied in large human populations. Human Mendelian randomization approaches have been highly informative in strengthening the link between low vitamin D status and development of diseases such as multiple sclerosis [194,195]. The complementary approach of investigating the non-skeletal health benefits of vitamin D through supplementation trials, despite their complexities and caveats, is also being highly informative in the human healthcare setting. For example, recent large trials have not shown any clear benefit in reduction of incidence of cardiovascular or cancer [196–198]. However, trials are revealing that vitamin D supplementation can be helpful in respiratory tract disorders, notably in patients with low 25(OH)D concentrations [199,200], and in improving survival times in patients diagnosed with cancer [201,202]. The global COVID-19 pandemic caused by SARS-CoV-2 has stimulated a flurry of interest into the role of vitamin D in both the treatment and prevention of this infection, with some studies postulating that a depleted vitamin D status could be associated with a worse outcome [203]. While these approaches may be challenging to undertake in the veterinary sector, long-term studies of healthy animals of known vitamin D status are necessary to further define the relationship between 25(OH)D concentrations and non-skeletal health outcomes in dogs and cats.

#### 5. Summary points

- Vitamin D metabolism disorders are a significant cause of morbidity and mortality in dogs and cats.
- The importance of vitamin D in the development and maintenance of skeletal health is well established in companion animals. There is a growing awareness of the potential role vitamin D may play in non-skeletal health in dogs and cats.
- The growth in vitamin D metabolite assays, which have been validated for use in companion animal samples, has greatly facilitated the rapid diagnosis of vitamin D disorders in dogs and cats.
- Both vitamin D deficiency and vitamin D excess disorders are well described in dogs and cats.

# Overview of vitamin D actions in cancer

Marjolein van Driel<sup>1</sup>, Alberto Muñoz<sup>2</sup> and Johannes P.T.M. van Leeuwen<sup>1</sup>

<sup>1</sup>Department of Internal Medicine, Erasmus MC, Rotterdam, the Netherlands <sup>2</sup>Instituto de Investigaciones Biomédicas “Alberto Sols”, Consejo Superior de Investigaciones Científicas, Universidad Autónoma de Madrid, CIBERONC and IdiPAZ, Madrid, Spain

## OBJECTIVES

- To introduce vitamin D and vitamin D receptor in cancer in a historical context.
- To provide insights into processes underlying vitamin D effects on cancer cells.
- To present developments in combinations of vitamin D with other therapies.
- To summarize the impact of vitamin D metabolism and tumor resistance.

## 1. Introduction

The seco-steroid hormone 1,25-dihydroxyvitamin D<sub>3</sub> [1,25(OH)<sub>2</sub>D<sub>3</sub>] is the most potent metabolite of vitamin D<sub>3</sub> and is an important regulator of calcium homeostasis and bone metabolism via actions in intestine, bone, kidney, and parathyroid glands. 1,25(OH)<sub>2</sub>D<sub>3</sub> exerts its effects via an intracellular receptor that is a member of the steroid hormone receptor family. Throughout the past decades, it has become evident that the vitamin D receptor (VDR) is not limited to cells and tissues involved in regulation of calcium and bone metabolism but is also present in a wide variety of other cells and tissues including cancer cells of various origins. This has led to a growing number of studies on the role of vitamin D in tumor cell growth regulation, treatment of cancer, and development of potent synthetic vitamin D analogs. The anticancer action of vitamin D may not only be limited to the cancer cells itself but also target other cells

in the tumor such as the stromal cells (fibroblasts, adipocytes, and immune and endothelial cells). Various specialized chapters will discuss in detail the effect of vitamin D on specific cancer types (see Chapters 85–92 in this section) and the development of analogs. In this chapter, our goal is to provide an overview of the history and current state of knowledge of the field. We will address several areas: recent developments in studies of vitamin D and cancer, regulation of tumor cells, possible mechanisms, and clinical applications. Since the field has become so vast of course, we could not cite all of the relevant papers, and the reader is referred to the specialized chapters on the various cancers that follow this chapter for more detail.

Note by the authors: We covered a broad range of topics and scientific literature. We realized that it is impossible to include and cite all literature available. Therefore, the reference list should be considered as incomplete, and it is expected that additional references can be found by searching on the various topics discussed. By no means, we had any prejudice in our selection of citation of particular studies.

## 2. Vitamin D and cancer

### 2.1 Vitamin D receptor

As exemplified in Table 84.1, the VDR has been demonstrated in a broad range of tumors and malignant cell types. VDR level is increased in ovarian carcinoma compared with normal ovarian tissue [1]. For colon and breast cancer cells, an inverse relationship between VDR level and degree of differentiation has been described by some investigators [2,3]. For colorectal cancer, it was shown that VDR expression is associated with

**TABLE 84.1** VDR in tumors and malignant cell types.

Basal cell carcinoma	Myeloid leukemia
Breast carcinoma	Multiple myeloma
Bladder cancer	Osteogenic sarcoma
Cervical carcinoma	Ovarian carcinoma
Colonic adenocarcinoma	Neuroblastoma
Colorectal carcinoma	Non-Hodgkin's lymphoma
Gall bladder carcinoma	Pancreatic carcinoma
Glioblastoma	Parathyroid adenoma
Kaposi sarcoma	Pituitary adenoma
Lung carcinoma	Prostate carcinoma
Lymphocytic leukemia	Renal cell carcinoma
Malignant B cell progenitors	Squamous cell carcinoma
Malignant melanoma	Transitional cell bladder carcinoma
Medullary thyroid carcinoma	Uterine carcinosarcoma

the degree of tumor differentiation [4] and with a more favorable prognosis [5]. Accordingly, VDR expression in colon tumor stromal fibroblasts predicted a favorable clinical outcome [6]. This is an important aspect of the anticancer actions of vitamin D: interacting with surrounding stromal cells including cells of the immune system and not only with the cancer cells. In pancreatic cancer, the VDR regulates transcription of pancreatic stellate cells, which results in stromal remodeling, which leads to reduced tumor volume and increased chemotherapeutic response [7]. In hepatocellular carcinoma, SQSTM1 (p62) protein was found to act as a negative regulator of liver inflammation and fibrosis through VDR signaling in hepatic stellate cells [8].

A VDR immunoreactivity score showed an increase in VDR in breast carcinoma specimens compared with normal breast tissue, but no clear relation with proliferative status could be assessed [9]. A later study by the same group showed that VDR expression is not a prognostic factor for breast cancer, but the strong VDR immunoreactivity in the breast cancer specimens supports the evidence that it may be a target for intervention [10]. Also in other studies, no associations between VDR concentration and clinical and biochemical parameters of breast cancer were found [11–13]. These outcomes could be the result of the fact that in clinical human breast tumor samples, variable expression of the VDR was found in different cohorts [14].

A phenomenon that should be taken into account is the intratumor heterogeneity. Single-cell sequencing techniques demonstrated that expression of genes may vary within a tumor, which may explain differences in responses to treatments [15,16]. Novel technological developments such as spatiotemporal single-cell sequencing will provide sequence data in relation to the location in the tumor and help understanding intratumoral heterogeneity [17]. This will also provide

insight into the relation between cancer cells, immune cells, and stroma within the tumor. These are all three targets for vitamin D, and it is conceivable that for VDR expression and vitamin D action, intratumoral heterogeneity is also important. Further illustration of the complex and potentially nonlinear relationship between VDR levels and cancer-related outcomes is shown by the report that both VDR high and VDR low groups show a reduced regression-free survival compared with the VDR normal group [18].

Albeit that the association studies on VDR expression and predictive and/or prognostic characteristics for cancer are so far not conclusive, depending also on other features such as VDR functionality or 25(OH)D levels, the widespread distribution of the VDR in malignant cells indicates that regulation of cancer cell function is an action of 1,25(OH)<sub>2</sub>D<sub>3</sub> and provides a molecular basis for the VDR and vitamin D level association studies. An interesting observation has put the VDR in relation to cancer in another perspective. It was shown that VDR can function as a receptor for the secondary bile acid lithocholic acid [19]. This compound is hepatotoxic and a potential enteric carcinogenic. Interestingly, binding of both lithocholic acid and vitamin D to the VDR results in induction of CYP3A, the enzyme that detoxifies lithocholic acid in the liver and intestine [19,20]. It is postulated that vitamin D and lithocholic acid, by binding to the VDR, activate a feed-forward catabolic pathway that increases CYP3A expression, leading to detoxification of carcinogenic bile acids. In addition to the option that other ligands than vitamin D may activate VDR, a recent mechanism brings forward that vitamin D metabolites may activate another nuclear receptor (LXR) [21]. This brings in the field of vitamin D metabolism beyond or besides CYP24A1 action and understanding their target tissue/tumor type-specific production, stability, and levels. The development in analytical tools, e.g., LC-MS/MS, allows more in-depth analyses of vitamin D metabolism, which may deliver a broad spectrum of metabolites [22].

Although cellular effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> traditionally have been attributed to activation of the nuclear VDR, over the years research has been performed to identify a membrane 1,25(OH)<sub>2</sub>D<sub>3</sub> receptor. Currently, protein disulphide isomerase family member 3 (PDIA3, or ERp57, or 1,25D<sub>3</sub>-MARSS) is the most likely candidate. For more detailed discussion on PDIA3, see 2020 Viewpoint article by Zmijewski and Carlberg [23].

### 2.1.1 Epidemiology

The first to document an association of cancer mortality with sun exposure and latitude was Hoffman in 1915 [24]. Later studies in 1980 by Garland et al. [25] provided additional data showing that death rates from colon cancer tended to increase with increasing latitude and

decreasing sunlight. The sunlight/ecological concept is discussed in [Chapters 56 and 85](#). Later, more direct evidence about a correlation between vitamin D concentration and colon cancer came from the inverse relationship between levels of serum 25-hydroxyvitamin 25(OH)D and the incidence of colon cancer [26,27]. In a metaanalysis, Gorham et al. [28] estimated that an increase of 84 nmol/L (33 ng/mL) in serum 25(OH)D level would lead to a 50% reduction in the incidence of colon cancer. A study of National Health and Nutrition Examination Survey III (NHANES III) data also found an association between 25(OH)D concentration and colorectal cancer mortality. Individuals with a 25(OH)D level over 80 nmol/L (32 ng/mL) had a 75% lower risk of death from colorectal cancer than those with lower levels of 25(OH)D. A concentration over 95 nmol/L correlated with a 55% reduction in colon cancer risk compared with those with a level below 40 nmol/L [29]. Several studies confirmed that a higher concentration of vitamin D was associated with lower colon cancer incidence and patients have a better overall survival [30].

From the NHANES III study, it was reported that women with a serum 25(OH)D concentration of more than 62 nmol/L had a 75% decrease in mortality due to breast cancer [29]. From two other studies, the authors concluded that there was a 58% lower risk of breast cancer in women with a 25(OH)D concentration of more than 95 nmol/L compared with women with levels lower than 37.5 nmol/L [31,32]. In a metaanalysis, 1750 women were stratified into five groups of 25(OH)D concentrations ranging from high to low, and this showed a clear dose–response association [33]. The highest breast cancer rates were found in the group with the lowest 25(OH)D concentration (<32 nmol/L), while the cancer rates were lower at higher levels (>130 nmol/L). Later studies confirmed the relationship between higher 25(OH)D levels and a lower risk for breast cancer progression and mortality [34]. A large Finnish epidemiological study showed an association of low serum 25(OH)D with prostate cancer [35,36]. The incidence of prostate cancer was twice as high in men with a 25(OH)D concentration below 70 nmol/L and 1,25(OH)<sub>2</sub>D<sub>3</sub> levels below 77 pmol/L. A full discussion of the epidemiologic data linking vitamin D and cancer can be found in Chapter 85, and a recent review by Munoz and Grant [37]. It is strongly suggestive that avoiding vitamin D deficiency may be a way to reduce cancer risk and progression [38].

Studies showed that the association between UVB irradiance and prostate cancer incidence depends on the season of irradiance [39], and an Australian study demonstrated a seasonal pattern for testicular germ cell cancer with the highest number of diagnosis in the winter [40]. However, it is difficult to envisage that cancer development and progression, which is often a long-

term, multistage process, depends on a 3-month period like winter within general lowest levels of 25(OH)D. The relationship between sunlight exposure and cancer, especially with respect to vitamin D, had been carefully reviewed earlier by Studzinski and Moore [41]. The dual relationship between sunlight and cancer is of interest and remains the subject of many studies [42–44]. A relation between skin type and prostate cancer has been described [45–47], and an article discussing the skin, sunlight, vitamin D and cancer from an evolutionary perspective has been published [48]. Grant et al. [49] estimated that between 50,000 and 63,000 Americans and between 19,000 and 25,000 adults from the United Kingdom die every year from cancer due to vitamin D deficiency. An analysis of the economic burden due to vitamin D insufficiency from inadequate exposure to solar UVB, diet, and supplements was \$40–56 billion in 2004 versus an economic burden for excess UV irradiation of \$6–7 billion [50]. In Multiple myeloma, lower 25(OH)D levels were associated with higher plasma cell number in the bone marrow, and a high incidence of vitamin D deficiency was found in myeloma patients [51].

The relationship between cancer, diet, calcium intake, and vitamin D has also been addressed in several studies [52–54]. A study on intake of micronutrients suggested that vitamin D and calcium might interact with antioxidants such as vitamin C and E in reducing colorectal cancer risk [55]. It is clear that sunlight exposure, vitamin D intake, and other dietary components such as calcium and fat should be considered as possibly interacting with one another when the relationship between vitamin D and cancer risk is assessed. The data on VDR as bile acid sensor and its postulated role in detoxification provide a direct biological basis for the relation between increased colon cancer and high-fat diets [56] and that colon cancer occurs in areas with higher prevalence of rickets [57]. In addition, mice lacking VDR have been reported to have a higher proliferation rate in the colon [58,59]. A survey of possible mutations in the VDR in osteosarcomas, several other sarcomas, non-small-cell lung cancers, and a large number of cell lines representing many tumor types did not show that mutations or rearrangements in the VDR gene play a role in these cancers [60]. Aspects of sunlight and the epidemiology of vitamin D and calcium will be discussed in greater detail in [Chapters 56 and 85](#).

However, data on the associations between vitamin D and cancer are not consistent. This has been observed in prostate cancer [34]. In a large prospective study by Ahn et al. [61] the hypothesis that vitamin D is associated with decreased risk of prostate cancer was not supported; in contrast, higher circulating 25(OH)D<sub>3</sub> concentrations may be associated with increased risk of aggressive disease. Also in other types of cancer, not

always the same association was found. In breast cancer, similar vitamin D intakes were found in breast cancer patients and control subjects [62]. Moreover, in a mouse model, no relationship was found between dietary intake of a wide range of doses of calcium or vitamin D on carcinogen-induced skin tumors [63].

Also for ovarian cancer, a similar discrepancy was observed. For example, Grant et al. [42,64] reported a strong association between vitamin D levels, geographical latitude, and ovarian cancer mortality, while more recently, Toriola et al. [65] in a case–control study with the Finnish Maternity Cohort did not find significant association between ovarian cancer and serum 25(OH)D<sub>3</sub> levels.

A concluding comment is that a high number, but by no means not all, observational, epidemiological, and pre-clinical studies suggest a protective anticancer action of vitamin D. The Cochrane review [66] warns for study bias due to low numbers of participants and selective groups of participants. A few aspects that need to be considered, as they may explain the not always consistent observations and can help to improve analyses and deepen our knowledge. First, what is sufficient and what is deficient? Criteria for sufficient and deficient are still related to classical end points in calcium and bone homeostasis. One can envisage that for cancer-related endpoints, different definitions of deficient and sufficient are needed. Second, associations are based on serum levels and then primarily on 25(OH)D levels. With new analytical tools and techniques, it is possible to produce a full vitamin D metabolic profile. These profiles can also be put into perspective of seasonal dynamics. In addition, the relationship between serum levels/serum metabolic profiles and target tissue or tumor levels/metabolic profiles should be taken into account [67]. Over the years, data have been accumulating on the relationship between obesity and vitamin D storage in adipose tissues on one hand and circulating levels of vitamin D on the other hand [68–71].

### **2.1.2 Genetic polymorphisms in the vitamin D system**

The majority of the genetic association studies have focused on variations in the VDR. Several polymorphisms have been identified in the VDR gene and studied in relation to various endpoints including osteoporosis and other diseases. Over the past 20–25 years, an increasing number of studies have been published focusing on the association of various polymorphisms in the VDR gene and different types of cancer. Overall, the size of these association studies is small and inadequate to control for confounding, consequently leading to a variety of inconclusive results. The cancer types investigated, a.o. prostate, breast, lung colorectal, skin, renal carcinoma, etc. are not

monogenetic disorders, and the impact of genetic variations will be small and dependent on interaction with polymorphisms in other genes and interaction with environmental factors. To reach robust conclusions on associations of polymorphisms with cancer incidence, progression, and/or treatment, large samples size studies are needed with uniform clinical endpoints and distinct description of phenotypic and environmental parameters. This will hopefully provide sufficiently powered studies for strong genotype–phenotype association analyses and gene–environment interactions as well as ethnic differences [72]. Combining genome-wide association studies in different cohort studies is an approach to follow, like the one on prostate cancer (BPC3) [73]. One of the conclusions by the authors is that more studies with larger numbers of participants are needed. An alternative intermediate step can be metaanalyses of the currently published smaller association studies. Recently, several attempts have been made in this direction [74–76] finding some associations but with a general conclusion that additional larger studies are needed. Publication bias is an important aspect to take into account with metaanalyses as studies showing an association are more likely published than those not showing an association.

Mendelian randomization (MR) is an increasingly popular approach to investigate the causal implications of gene variants and thereby to translate correlation to causation. At least 17 articles with MR in the title have been published from 2016 to 22 in the field of vitamin D and cancer. However, also for vitamin D and cancer, MR study sample size is important and challenging to identify a strong genetic marker and make these studies feasible. Vitamin D–cancer MR studies focused mainly on the relationship between genetic variants and circulating 25(OH)D levels and indirectly with cancer outcome (see, for example [77]). Following this, from the initial focus on VDR polymorphisms, an increasing number of studies include vitamin D metabolizing enzymes, including DHCR7, CYP2R1, CYP27B1, and CYP24A1 (e.g., Refs. [78–80]). But also here the aforementioned comments on sample size and phenotypic description are valid and important for robust conclusions. Further detailed discussion of associations, possible functional consequences of VDR, other gene polymorphisms, and impact of vitamin D levels are beyond the scope of this chapter but will be addressed in greater detail in Chapter 61.

## **2.2 Growth, development, and carcinogenesis**

In addition to the epidemiological studies and demonstration of VDR in cancer cells, since the early 1980s, there is also an increasing amount of cell

biological data supporting a role for vitamin D as an inhibitor of cancer growth [38,81–83]. Multiple studies have shown that at elevated concentrations ( $10^{-9}$ – $10^{-7}$  M),  $1,25(\text{OH})_2\text{D}_3$  inhibits the growth of tumor cells in vitro. It was demonstrated as early as 1981 that  $1,25(\text{OH})_2\text{D}_3$  inhibits the growth of malignant melanoma cells and stimulates the differentiation of immature mouse myeloid leukemia cells in culture [84–86].  $1,25(\text{OH})_2\text{D}_3$  also induces differentiation of normal bone marrow cells. Immature bone marrow cells of the monocyte–macrophage lineage are believed to be the precursors of osteoclasts, and  $1,25(\text{OH})_2\text{D}_3$  induces differentiation of immature myeloid cells toward monocytes–macrophages and also stimulates the activation and fusion of some macrophages. From these results, it has been postulated that  $1,25(\text{OH})_2\text{D}_3$  stimulates differentiation and fusion of osteoclast progenitors into osteoclasts [87–89]. These in vitro findings were followed by the in vivo observation that  $1,25(\text{OH})_2\text{D}_3$  prolongs the survival time of mice inoculated with myeloid leukemia cells [90]. As shown in Table 84.2, over the years,  $1,25(\text{OH})_2\text{D}_3$  has been shown to have beneficial effects in several other in vivo animal models of various types of cancers [91–113]. For more recent reviews for breast, colon, and prostate cancers, see Chapters 88, 89 and 91.

A relationship between vitamin D, the presence of VDR and carcinogenesis was shown for the skin. Absence of VDR increased the sensitivity for chemically induced tumorigenesis [114]. Vitamin D compounds protect against UV-induced DNA damage and photocarcinogenesis and reduce ROS/RNS to limit UV-induced suppression of immune response [115]. Moreover, in mice, the vitamin D analog EB1089 prevented  $\beta$ -catenin-induced trichofolliculomas, while low levels of VDR associated with the induction by  $\beta$ -catenin of infiltrative basal cell carcinomas [116]. The  $\beta$ -catenin as well as the Hedgehog signaling and the recently found lncRNA pathways underly the protective role of the VDR as a tumor suppressor in the skin [117,118]. In addition, regulation of *c-MYC* by the VDR may lie at the basis for cancer preventive actions [119]. In stroma from pancreatic tumors, the VDR is a master transcriptional regulator of the conversion to quiescent cells after calcitriol treatment, leading to reduced tumor volume and increase in survival compared with chemotherapy [7]. Also for prostate, colon, and liver, a protective role for vitamin D in carcinogenesis has been described [120–122]. A study with aging (up to 600 days) wild type and CYP27B1 knockout mice demonstrated that  $1,25(\text{OH})_2\text{D}_3$  deficiency leads to accelerated tumor initiation and growth. This is related to elevated oxidative stress, activating oncogenes, inactivation of tumor suppressor genes, and alteration of cellular senescence in tumor microenvironment [123]. An interesting area that

needs further exploration is the interplay between oral microbiota and oropharyngeal squamous cell carcinogens and the role of vitamin D herein [124]. A preclinical study reported vitamin D preventive effects on oral carcinogenesis, which depends on timing and duration of treatment implicating a limiting role for CYP24A1 [125].

An important aspect and limitation of the treatment of cancer with  $1,25(\text{OH})_2\text{D}_3$  to achieve growth inhibition are the relatively higher doses of  $1,25(\text{OH})_2\text{D}_3$  needed (confirming the in vitro data), which can cause the side effect of hypercalcemia (see Section 2.3). This has prompted the development of analogs of  $1,25(\text{OH})_2\text{D}_3$  in an attempt to dissociate the antiproliferative effect from the calcemic and bone metabolism effects. Although the precise mechanism for this dissociation of activities is not completely understood, at the moment several  $1,25(\text{OH})_2\text{D}_3$  analogs are available that seem to fulfill these criteria. In Table 84.3, the in vivo animal studies using  $1,25(\text{OH})_2\text{D}_3$  analogs on various cancer types are summarized [101,107,108,110–113,126–144].

## 2.3 Clinical studies

Only a limited set of clinical trials of vitamin D in cancer have been performed up to now. We will mention a few examples here. Further discussion on clinical trials can be found in the chapters on the specific malignancies that follow. Alfacalcidol ( $1\alpha$ -hydroxyvitamin  $\text{D}_3$ ;  $1\alpha$ -(OH) $\text{D}_3$ ), which is converted to  $1,25(\text{OH})_2\text{D}_3$  in vivo, caused a beneficial response in low-grade non-Hodgkin's lymphoma patients [145,146]. Also, in a study treating myelodysplasia patients with alfacalcidol, transient improvement in peripheral blood counts was seen; however, half of the patients developed hypercalcemia [147]. Another study reported a sustained hematological response in six myelodysplasia patients treated with high doses of alfacalcidol [148]. These patients were restricted in their dietary calcium intake; nevertheless, four patients developed hypercalcemia due to increased bone resorption. With respect to treatment of cutaneous T cell lymphoma with a combination of  $1,25(\text{OH})_2\text{D}_3$  and retinoids, contrasting results have been obtained. It has been suggested that the variability was due to differences in phenotype of the various lymphomas [149–151].

A study on early recurrent prostate cancer showed that daily treatment with  $1,25(\text{OH})_2\text{D}_3$  slowed the rise in prostate-specific antigen (PSA) [152]. Using a regime of once weekly treatment with very high-dose calcitriol was found to be safe but did not result in a significant reduction in PSA in prostate cancer cells [153]. Two studies were specifically designed to examine the route

**TABLE 84.2** In vivo effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> and 1 $\alpha$ -(OH)D<sub>3</sub> in animal models of cancer.<sup>a</sup>

Tumor	Model	Effect	Refs
Adenocarcinoma	CAC-8 cells injected in nude mice	Reduction in tumor volume	[111]
Breast	NMU- and DMBA-induced breast cancer in rats Injection of fibroblasts from human breast tumors in nude mice and injection of treated mammospheres	Tumor suppression Reduced tumor volume	[97,100] [565]
Colon	Human colon cell line implanted into nude mice; DMH-induced colon cancer in rats; APCmin mice	Tumor suppression; reduction of the incidence of colon adenocarcinomas; decrease in polyp number and tumor load	[94,96,99,600]
Kaposi sarcoma	KS Y-1 cells implanted in nude mice	Tumor growth retardation	[109]
Leydig tumor	Leydig cell tumor implanted into rats	Tumor suppression	[101]
Liver tumor	Injection of liver carcinogen diethylnitrosamine in mice and low vitamin D diet	Increase in tumor growth	[436]
Lung	Implantation of Lewis lung carcinoma into mice	Reduction of the number of metastases (without suppression of primary tumor); tumor suppression; increased antitumor immunity	[91,105,466,601]
Melanoma	Human melanoma cells implanted into nude mice	Tumor suppression	[94]
Osteosarcoma	Human osteosarcoma cells implanted into nude mice	Tumor suppression	[102]
Prostate	Dunning MAT LyLu rat prostate model; LNCaP xenografts in nude mice; PAIII tumors in Lobund-Wistar rats	Reduction in lung metastasis; tumor suppression	[107,108,110,112,113]
Retinoblastoma	Retinoblastoma cell line implanted into nude mice; transgenic mice with retinoblastoma	Tumor suppression	[95,98]
Walker carcinoma	Walker carcinoma cells injected in rats	Tumor suppression	[104]
Skin	DMBA/TPA-induced skin tumors in mice Human squamous cell carcinoma cells (A431) injected in nude mice	Inhibition of tumor formation Tumor cell death	[92,93] [495]

<sup>a</sup>The dosage, duration of treatment, diet, and effects on serum/urinary calcium vary among the studies. DMBA, 7,12-dimethylbenz[a]anthracene; DMH, 1,2-dimethylhydrazine dihydrochloride; NMU, nitrosomethylurea; TPA, 12-O-tetradecanoylphorbol-13-acetate.

and schedule of administration and calcemic response in patients with advanced malignancies [154,155]. The set of trials using very high dose 1,25(OH)<sub>2</sub>D<sub>3</sub> plus taxotere in advanced prostate cancer is discussed in Chapter 91 on prostate cancer (Nonn & Campbell) and has recently been reviewed [156].

Clinical trials using vitamin D analogs have been initiated over the past years. However, these were

mostly limited clinical trials focusing on small groups of patients for whom regular treatment had failed. Only a relatively few studies have been published. The analog calcipotriol (Daivonex/Dovonex/MC903) has been used for topical treatment of advanced breast cancer; however, several of the patients still developed hypercalcemia [157]. Studies have been carried out in advanced breast cancer [158] and pancreatic cancer

[159], but the clinical results were limited. In a single case of Kaposi sarcoma and topical application of calcipotriol, success in tumor regression was reported [109]. Also the impact of inhibition of CYP24A1 to enhance the anticancer activity of vitamin D has been studied, and a potentiation of the vitamin D effect was found as has been shown previously in vitro [160]. Data on clinical studies with vitamin D and vitamin D analogs are reviewed by Vijayakumar [161,162], Feldman [38], Giammanco [163], and Scaranti [164].

More well-designed, sufficiently powered randomized double-blind placebo-controlled trials with primary cancer-related endpoints are necessary to overcome some unsolved issues in previous studies involving younger participants, men/women, and taking into account individual vitamin D status, duration of treatment, dosage levels, and longer follow-up of all participants. Metaanalysis of randomized controlled trials is an alternative approach like the recent one for breast cancer [165]. This analysis led to the conclusion

that there is insufficient evidence to support efficacy of vitamin D supplementation but the cautionary comments on metaanalysis mentioned in the [Section 2.1.2](#) also hold for the clinical trials.

Together, limitations in study design may be part of the explanation of the unambiguous clinical study results, but it can also reflect that vitamin D on its own may not be a strong and primary anticancer drug.

## 2.4 Angiogenesis and metastasis

For the tumor suppressive activity of vitamin D<sub>3</sub> compounds *in vivo*, besides growth inhibition and differentiation, two additional aspects contribute to potential benefits including effects on (1) angiogenesis and (2) invasion and metastasis. First, we will discuss vitamin D and angiogenesis. Angiogenesis is an essential requirement for the growth of solid tumors. Compounds that inhibit angiogenesis might therefore contribute to anti-tumor therapy. Antiangiogenic drugs may lead to inhibition of tumor progression, stabilization of tumor growth, tumor regression, and prevention of metastasis. Antiangiogenic effects may play a role in the tumor suppressive activity of vitamin D<sub>3</sub> compounds [166]. The effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on angiogenesis may be due to inhibition of tumor cell proliferation, resulting in fewer angiogenic cells. However, inhibition of angiogenesis could also be observed when the tumor cells were treated *in vitro* with 1,25(OH)<sub>2</sub>D<sub>3</sub> and, after cell washing, were injected into mice [167]. Under these conditions, both control and 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated mice were injected with similar numbers of cells. Therefore, these data indicate that 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits the release of angiogenic factors (vascular endothelium growth factor, transforming growth factor- $\alpha$ , basic fibroblast growth factor, epidermal growth factor, etc.) or stimulates antiangiogenic factors. 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment caused a reduction in the angiogenic signaling molecule, angiopoietin-2 in squamous cell carcinoma, and radiation-induced fibrosarcoma-1 cells [168]. 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited both VEGF production and HIF1 $\alpha$  transcriptional activity in cancer cells of various origins under both normoxic (20% oxygen) and hypoxic (1% oxygen) conditions [169]. 1,25(OH)<sub>2</sub>D<sub>3</sub> also reduced HIF1 $\alpha$  and VEGF in an *in vivo* prostate tumor model, which was accompanied by an abnormal tumor angiogenesis. This was only observed in wild-type but not in VDR knockout tumors [170]. In retinoblastomas in mice, 1,25(OH)<sub>2</sub>D<sub>3</sub> has also been shown to reduce angiogenesis [171].

A study by Oades et al. [112] however, showed that the 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs EB1089 and CB1093 inhibited tumor growth in two prostate animal models but did not inhibit angiogenesis in a rat aorta assay. Whether this implicates that vitamin D affects angiogenesis in

a tumor situation and not in a nonmalignant condition is not clear. This may resemble the effects of endostatin, which inhibits pathological but not normal vascularization [172,173]. In support of this possibility is the finding that 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs EB1089, Ro-25-6760, and ILX23-7553 potently inhibit growth of endothelial cells derived from tumors but are less potent against normal aortic or yolk sac endothelial cells [168]. In SW480-ADH colon cancer cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> has a complex regulatory effect on the angiogenic phenotype: it increases the expression of VEGF and TSP-1 and regulates Id genes, but not that of PDGF-B, through the activation of their respective promoters [174]. An interesting observation is that also deglycosylated vitamin D-binding protein (DBP-maf) has been reported to inhibit angiogenesis [175,176] and to inhibit growth of pancreatic tumors in nude mice [176]. Whether 1,25(OH)<sub>2</sub>D<sub>3</sub> may interfere with DBP-maf in tumor growth inhibition and antiangiogenesis remains to be established. Interaction with another factor, interleukin-12, in the inhibition of angiogenesis has been reported [177]. The data so far show that interference with angiogenesis is a general effect of vitamin D, via effects either direct on endothelial cells or indirectly via effects on the cancer cells.

A mechanism of antitumor activity to be discussed, and one related to angiogenesis, is invasion and metastasis. Metastasis is the primary cause of the fatal outcome of cancer diseases. A study by Mork Hansen et al. [178] indicated that 1,25(OH)<sub>2</sub>D<sub>3</sub> may be effective in reducing the invasiveness of breast cancer cells. They showed that 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the invasion and migration of a metastatic human breast cancer cell line (MDA-MB-231) using the Boyden chamber invasion assay. In support of this, it was shown that 1,25(OH)<sub>2</sub>D<sub>3</sub>, and the analogs KH1060, EB1089, and CB1093, all inhibited secretion of tissue-type and urokinase plasminogen activator and increased plasminogen activator inhibitor 1 (PAI-1) in the MDA-MB-231 metastatic breast cancer cell line [179].

In line with decreasing the capability of breast cancer cells to metastasize, 1,25(OH)<sub>2</sub>D<sub>3</sub> also inhibited the epithelial–mesenchymal transition, an important step in metastatic behavior [180]. Current understanding of the role of vitamin D in the epithelial–mesenchymal transition is reviewed by Munoz and coworkers [181–183]. Since then, multiple new studies have been published further demonstrating the vitamin D inhibition of epithelial–mesenchymal transition in a variety of cancer types. Among others, Horas et al. [184] demonstrated a role for the VDR in preventing epithelial–mesenchymal transition. Noncoding RNAs are important regulators in cellular (patho)physiology. The mir1204 stimulates tumor growth and targets VDR. Silencing of mir1204 increased expression of

VDR mRNA. VDR and mir1204 oppositely regulate cancer cell proliferation, metastasis, and epithelial–mesenchymal transition [185].

The vitamin D analog EB1089 also prevented skeletal metastasis in vivo and prolonged survival time in nude mice transplanted with human breast cancer cells [186]. Interestingly, it was shown that vitamin D deficiency promotes the growth of human breast cancer cells in the bones of nude mice [187]. This metastatic behavior in vitamin D deficiency is tumor autonomous and involves abrogation of the expression of the tumor progression gene Id1 [188].

Interestingly, the “prohormone” 25(OH)D could delay neoplasia, tumor growth, and metastasis in a non-immunodeficient MMTV-PyMT mouse model of metastatic breast cancer [189].

Vitamin D also inhibited the invasive ability of human prostate cancer cell lines, LNCaP, PC-3, and DU 145. 1,25(OH)<sub>2</sub>D<sub>3</sub> decreased MMP-9 and cathepsins, but not plasminogen activities, while it increased the activity of tissue inhibitors of metalloproteinase-1 (TIMP-1) and cathepsin inhibitors [190]. An intriguing observation is the interplay between VDR and TRPV5 in metastasis of renal cell carcinoma. TRPV5 plays a crucial role in renal calcium reabsorption, and its expression is directly upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [191,192]. However, in renal carcinoma cell lines, VDR knockdown led to increased TRPV5 expression accompanied by an increase in proliferation and migration while additional knockdown of TRPV5 reversed these effects on the tumor cells [193].

In an in vivo study, it was shown that 1,25(OH)<sub>2</sub>D<sub>3</sub> reduces the metastasis to the lung of subcutaneously implanted Lewis lung carcinoma cells [105]. In two animal models of prostate cancer, 1,25(OH)<sub>2</sub>D<sub>3</sub> and the analogs EB1089 and RO25-6760 inhibited lung metastases [107,108]. In these models, the tumors were implanted subcutaneously, and therefore, in contrast to the model of direct tumor cell injection in the left ventricle [194], no bone metastases occurred. In pancreatic cancer, the vitamin D analog MART-10 as well as 1,25(OH)<sub>2</sub>D<sub>3</sub> repressed migration and invasion of tumor cells via blocking the epithelial–mesenchymal transition [195]. MART-10 was also reported to repress metastases of head and neck squamous carcinoma cells and migration of breast cancer cells [196,197]. MART-10 inhibited VEGF-A-induced breast cancer and neuroendocrine tumor cell migration, suggestive of the interplay in control of angiogenesis and metastasis [198].

A fact to be considered in relation to metastasis is that bone is the most frequent site of metastasis of advanced breast and prostate cancer. There are some indications from clinical studies that bone metastases develop preferentially in areas with high bone turnover [199,200]. In contrast, agents that inhibit bone resorption such as

bisphosphonates and Denosumab have been reported to reduce the incidence of skeletal metastasis and improve survival [201–204]. Promising are also studies that focus on bone anabolic therapies [205]. Akech et al. [206] showed that Runx2 is a key regulator of events associated with prostate and breast cancer metastatic bone disease. Runx2 is intimately involved in vitamin D actions in osteoblast development [207]. As 1,25(OH)<sub>2</sub>D<sub>3</sub> may stimulate bone turnover, treatment of cancer with 1,25(OH)<sub>2</sub>D<sub>3</sub> might theoretically increase the risk of skeletal metastases. 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits breast cancer cell migration toward a bone environment in an in vitro bone metastasis model [208]. However, this in vitro model only focuses on the direct 1,25(OH)<sub>2</sub>D<sub>3</sub> effects on cancer cells but lacks any effect of vitamin D on bone turnover. Further studies in in vitro models that more closely resemble the in vivo situation and/or in vivo studies are needed to address this aspect of 1,25(OH)<sub>2</sub>D<sub>3</sub> therapy. Considering the use of vitamin D<sub>3</sub> analogs with reduced calcemic activity or treatment with vitamin D<sub>3</sub> in combination with other compounds to reduce bone turnover may be helpful (see Section 4). The versatile aspects of endocrine interplay (including vitamin D) in the cross-talk between bone cells and metastatic cancer cells are reviewed by Hofbauer et al. [209].

1,25(OH)<sub>2</sub>D<sub>3</sub> decreased androgen-stimulated progression of prostate cancer, but prolonged treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> increased metastatic behavior in a model of transgenic adenocarcinoma of mouse prostate (TRAMP). This shows the need for further mechanistic studies to elucidate these both antineoplastic as well as prometastatic effects of vitamin D in prostate cancer [210]. Increased metastasis has also been observed in a 4T1 breast cancer mouse model after 1,25(OH)<sub>2</sub>D<sub>3</sub> or the analogs PRI-2191 and PRI-2205 treatment [211,212]. The authors study the effects on the immune cells in the tumor microenvironment and explain the increased metastasis by immunosuppressive effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> and analogs [212]. These data further stress the significance to focus on the complete composition of the tumor including cancer, stromal, and immune cells to fully understand and eventually predict a beneficial effect of vitamin D in cancer treatment.

## 2.5 Parathyroid hormone–related peptide

1,25(OH)<sub>2</sub>D<sub>3</sub> and parathyroid hormone (PTH) mutually regulate synthesis and secretion of one another. Production and secretion of PTH are inhibited by 1,25(OH)<sub>2</sub>D<sub>3</sub> via a transcriptional effect, and a vitamin D responsive element (VDRE) in the promoter of the PTH gene has been identified [213,214]. Parathyroid hormone–related peptide (PTHrP) was initially isolated

from several carcinomas and is responsible for the syndrome of humoral hypercalcemia of malignancy [215,216]. Although originally identified in carcinomas, PTHrP has also been identified in normal cells. As will be discussed now, vitamin D effects to inhibit PTH and PTHrP may have a role in its anticancer actions and in reducing metastases to bone [217,218].

In normal human mammary epithelial cells,  $1,25(\text{OH})_2\text{D}_3$  did not affect basal but inhibited growth factor–stimulated PTHrP expression via an effect on transcription [219]. In normal keratinocytes,  $1,25(\text{OH})_2\text{D}_3$  had no effect on PTHrP secretion in basal culture conditions [220] but did inhibit growth factor–stimulated PTHrP production as well [221]. Likewise,  $1,25(\text{OH})_2\text{D}_3$  as well as the analogs 22-oxacalcitriol and MC903 inhibited PTHrP secretion in immortalized human keratinocytes (HPK1A), but this inhibition was less in the more malignant ras-transfected clone HPK1A-ras [222,223].  $1,25(\text{OH})_2\text{D}_3$  and the analogs EB1089 and 22-oxacalcitriol inhibited the PTHrP gene transcription in and release from the squamous cancer cell line NCI H520 [224].

In the human T cell lymphotropic virus type I (HTLV-I)–transfected T cell line MT-2,  $1,25(\text{OH})_2\text{D}_3$  and 22-oxacalcitriol inhibited PTHrP gene expression and PTHrP secretion [225] and in rat H-500 Leydig tumor cells [226]; and  $1,25(\text{OH})_2\text{D}_3$  inhibited PTHrP secretion by PC-3 prostate cancer cells. However, another study demonstrated a prostate cancer–specific or cell-specific effect. Vitamin D and the analog EB1089 inhibited the PTHrP expression via a negative VDRE in LNCaP but not in PC3 prostate cancer cells [227,228]. It was suggested that this might play a role in the growth inhibition by vitamin D as PTHrP stimulates prostate cancer growth, tumor invasion, and metastasis [229–231]. In vivo observations comparable with these in vitro observations have also been made. When H-500 Leydig tumor cells were implanted in Fisher rats, treatment with  $1,25(\text{OH})_2\text{D}_3$  and the analog EB1089 resulted in reduced levels of tumor PTHrP mRNA and PTHrP serum levels [101]. EB1089 also reduced serum levels of PTHrP in nude mice implanted with squamous cancer cells [232].

In Fisher rats implanted with the Walker carcinoma,  $1,25(\text{OH})_2\text{D}_3$  caused a decrease in serum PTHrP, but the ratio of PTHrP levels and tumor weight was similar in rats receiving vehicle or  $1,25(\text{OH})_2\text{D}_3$ . The data point to an indirect effect on PTHrP via growth inhibition. However, the PTHrP mRNA levels appeared to be decreased by  $1,25(\text{OH})_2\text{D}_3$  [104]. In nude mice bearing the FA-6 cell line of a pancreas carcinoma lymph node metastasis, 22-oxacalcitriol inhibits PTHrP gene expression, which is related to inhibition of tumor-induced hypercalcemia [233]. Together, the overall picture that emerges from these studies is that an important

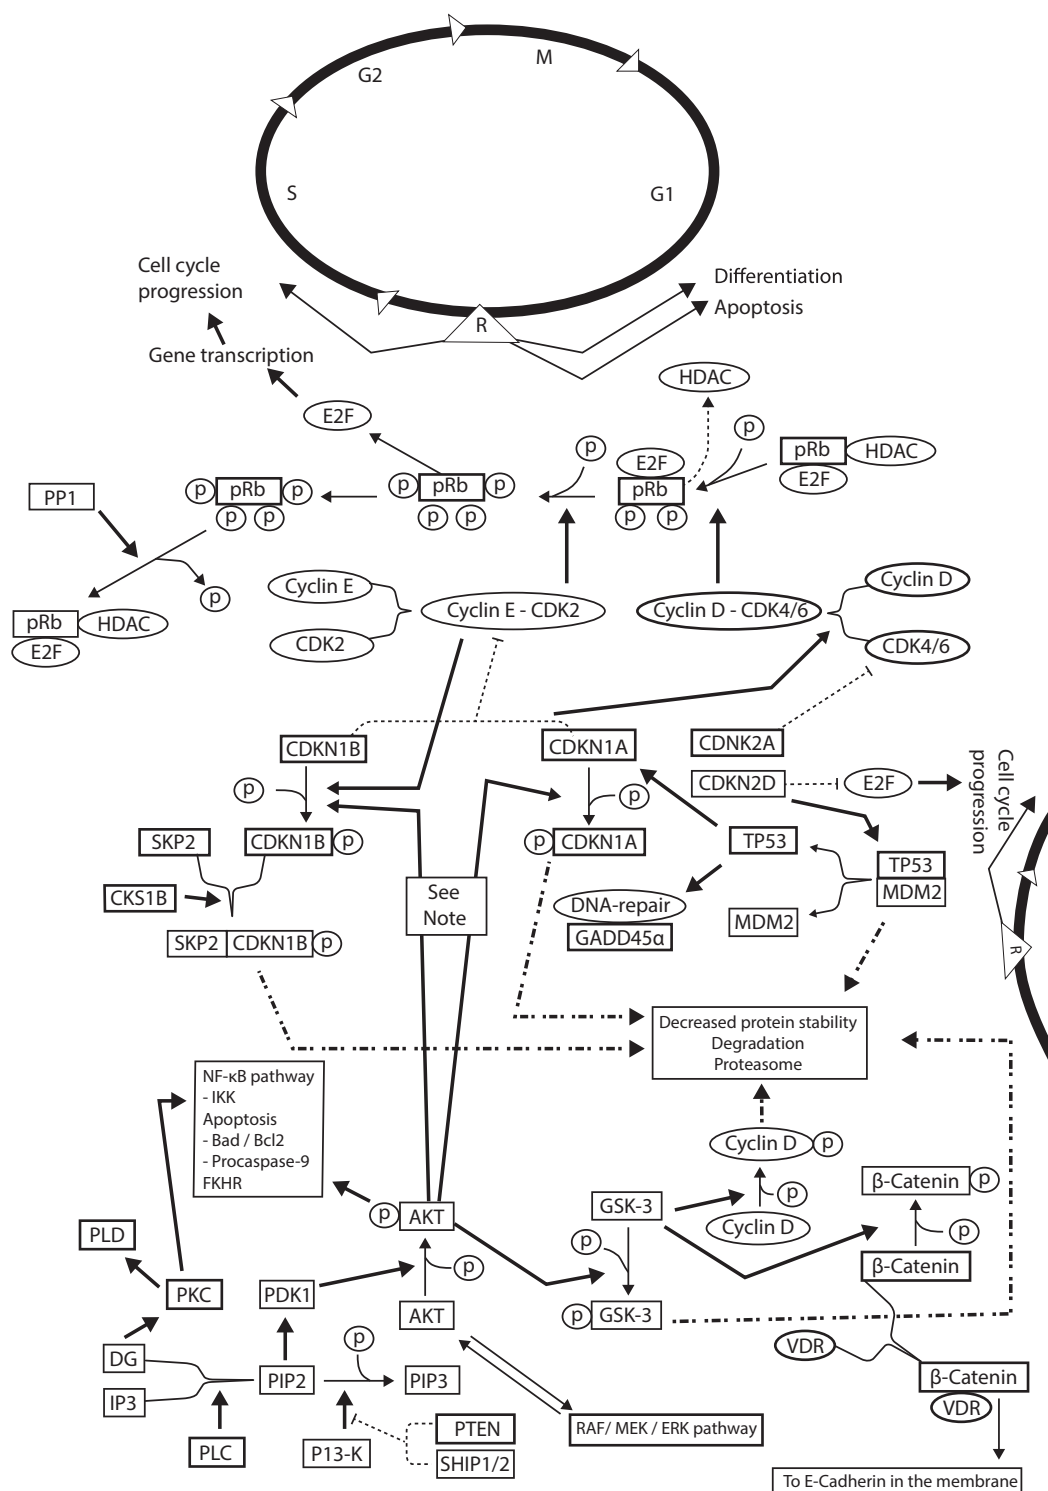

additional anticancer effect of vitamin D and analogs could be the inhibition of the humoral hypercalcemia of malignancy. However, also studies emerged reporting that PTHrP and  $1,25(\text{OH})_2\text{D}_3$  are both causing tumoral hypercalcemia. PTHrP and  $1,25(\text{OH})_2\text{D}_3$  were shown to be cosecreted in a non-Hodgkin's lymphoma patient and both together with hypercalcemia normalized after chemotherapy [234].

In contrast to these inhibitory effects in human tumor cells and tumor models, a stimulatory effect of  $1,25(\text{OH})_2\text{D}_3$  and EB1089 on PTHrP gene transcription and PTHrP production by a canine oral squamous carcinoma cell line (Sec 2/88) has been observed [235,236]. Also in vivo with the canine adenocarcinoma CAC-8 in nude mice, stimulation of PTHrP by  $1,25(\text{OH})_2\text{D}_3$  and EB1089 was observed [236]. These data indicate that the effect of vitamin D and analogs on canine tumors differs from that on human tumors.

### 3. Vitamin D effects on tumor cells

#### 3.1 Molecular action: (proto)-oncogenes and tumor suppressor genes

Oncogenes and tumor suppressor genes generally are involved in control of the cell cycle and apoptosis. One of the most widely studied oncogenes in relation to vitamin D is *c-MYC*. *c-MYC* suppresses expression of cell cycle/growth arrest genes *gas1*, *CDKN2B* (p15), *CDKN1A* (p21), *CDKN1B* (p27), and *gadd34*, *gadd45*, and *gadd153* [237] and has been postulated to play an early role in the following cascade of events in  $G_1$ : cyclins activate cyclin-dependent kinases (CDKs), which in turn can phosphorylate the retinoblastoma tumor suppressor gene product (p110<sup>RB</sup>), resulting in transition from  $G_1$  to S phase (see Fig. 84.1). In several cancer cell types,  $1,25(\text{OH})_2\text{D}_3$  has been reported to decrease *c-MYC* oncogene expression [238]. Analysis of HL-60 sublines showed a relation between reduction of *c-MYC* expression and inhibition of proliferation [239]. Similar observations were made for neuroblastoma cells treated with  $1,25(\text{OH})_2\text{D}_3$ , EB1089, and KH1060 [240]. The mechanism of *c-MYC* inhibition appears to be both direct, by inducing the binding of proteins to an intron element and the involvement of HOXB4 [241,242], and at least in colon cancer cells also indirect via the inhibition of the transcriptional activity of  $\beta$ -catenin and T cell factor (TCF) complexes [243]. In earlier studies, we did not observe a  $1,25(\text{OH})_2\text{D}_3$ -induced change in *c-myc* expression in MCF-7 and ZR-75.1 breast cancer cells while they were both growth inhibited [244], and a similar observation has been made for the colon adenocarcinoma CaCo-2 cell line [245]. Nontransformed embryonic fibroblasts are growth inhibited by

**FIGURE 84.1** Schematic representation summarizing the intracellular pathways and signaling pathways involved regulation of the cell cycle shown to be regulated by  $1,25(\text{OH})_2\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  analogs in regulating cell proliferation. Targets shown to be affected by  $1,25(\text{OH})_2\text{D}_3$  and/or its analogs are indicated in the bold boxes and ovals. Bold arrows and fine dotted lines indicate stimulation and inhibition, respectively. Coarse dotted lines indicate processing to the proteasome. p indicates phosphorylation. The effects on these cellular targets are not demonstrated in all types of cancer cells, but this diagram is aimed to give an overview of demonstrated targets and potential targets. Note: Dependent on the site of phosphorylation proteins can either be destabilized or degraded or be stabilized and activated. For example, phosphorylation of CDKN1A at T145 by AKT leads to degradation, while phosphorylation of S146 by AKT leads to increased stability. *AKT* (*PKB*), Protein kinase B; *Bad*, BCL2-antagonist of cell death; *Bcl2*, B cell leukemia/lymphoma 2; *Cdk*, Cyclin-dependent kinase; *CKS-1*, Cyclin kinase subunit 1; *DG*, Diacylglycerol; *E2F*, transcription factor; *ERK*, Extracellular signal-regulated kinase; *FKHR* (*AFX/FOX*), Forkhead family of

1,25(OH)<sub>2</sub>D<sub>3</sub>, whereas *c-myc* is not changed or is even increased [246,247]. In the MG-63 osteosarcoma cell line, 1,25(OH)<sub>2</sub>D<sub>3</sub> has been shown to enhance *c-MYC* expression [248], whereas we observed growth inhibition by 1,25(OH)<sub>2</sub>D<sub>3</sub> [249]. Likewise, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits proliferation and increases *c-MYC* expression in fibroblasts from psoriatic patients [250].

In a recent study, inhibition of *c-myc* was implicated as playing a major role in the ability of 1,25(OH)<sub>2</sub>D<sub>3</sub> to inhibit prostate cancer proliferation [251]. As an underlying mechanism, 1,25(OH)<sub>2</sub>D<sub>3</sub> and the VDR regulate the functional balance of *c-MYC* and its repressor MAD1/MXD1, to suppress *c-MYC* function [119].

Collectively, these data show that regulation of *c-myc* expression may be part of growth inhibition by vitamin D but that this is not generally applicable to all cells. 1,25(OH)<sub>2</sub>D<sub>3</sub> has also been reported to regulate expression of other oncogenes [252–254]; however, these data are rather limited. Nevertheless, it is clear that 1,25(OH)<sub>2</sub>D<sub>3</sub> has effects on the expression of various proto-oncogenes. The data so far are not conclusive with respect to which genes are crucial in the growth inhibitory action of 1,25(OH)<sub>2</sub>D<sub>3</sub>. This can be attributed to the fact that these (proto)oncogenes encode for transcription factors, growth factor receptors or components, or intracellular signaling cascades. The effects of these genes may differ between cells dependent on the presence or absence of additional cell type–specific conditions. Therefore, their postulated role is often complex. For example, increased *c-MYC* expression can be related to induction of apoptosis but also to stimulation of cell cycle progression. Interestingly, in oncogene-induced senescence, functional relationships were revealed between Ras, the vitamin D/VDR axis, and DNA repair factors [255].

In contrast to the oncogenes, the effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on tumor suppressor genes like the retinoblastoma gene is much clearer. This may be related to the fact that, in contrast to oncogenes, retinoblastoma and TP53 take well-defined positions in the control of cell cycle and DNA repair (see Fig. 84.1). The p110<sup>RB</sup> retinoblastoma gene product can either be phosphorylated or dephosphorylated. In the phosphorylated form, it can activate several transcription factors and causes transition to S phase and DNA synthesis [256]. In human chronic myelogenous leukemia cells [257], breast cancer cells [258], and HL-60 cells [259,260], 1,25(OH)<sub>2</sub>D<sub>3</sub> caused a dephosphorylation of p110<sup>RB</sup>, which is related to growth

inhibition and cell cycle arrest in G<sub>0</sub>/G<sub>1</sub> and in one study also in G<sub>2</sub> [260]. In the leukemic cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> also caused a reduction in the cellular level of p110<sup>RB</sup> [257,259]. In nontransformed keratinocytes, 1,25(OH)<sub>2</sub>D<sub>3</sub> induced dephosphorylation of p110<sup>RB</sup> as well [261]. The other major tumor suppressor gene is TP53 (*p53*). For leukemic U937 cells, it was reported that presence of TP53 is important for 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation [262]. In rat glioma cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> induces expression of TP53 [263]. However, 1,25(OH)<sub>2</sub>D<sub>3</sub> can inhibit cell growth and induce differentiation in cancer cells with defective TP53 [264], and also TP53-independent induction of apoptosis by EB1089 has been demonstrated [265]. These latter observations might be explained by the fact that vitamin D also interferes at levels in the cascade of cell cycle control downstream of TP53 (see Fig. 84.1). Recently, novel interesting data were added to the story of TP53 and 1,25(OH)<sub>2</sub>D<sub>3</sub> [266]. It was shown that a mutant TP53, often present in tumors, physically and functionally interacts with VDR. Mutant TP53 is recruited to vitamin D target genes and can stimulate gene expression and relieve suppression of other genes. Mutant TP53 increases nuclear accumulation of VDR and transforms vitamin D into an antiapoptotic agent [266]. An interesting unique relationship between tumor suppressor genes and vitamin D has recently been shown for the Wilms' tumor suppressor gene WT1. This zinc finger–containing transcription factor induces transcription of the VDR gene [267].

Several interesting additional genes, interactions and vitamin D targets in cancer treatment should be mentioned. It has been demonstrated that 1,25(OH)<sub>2</sub>D<sub>3</sub> can trigger NF-κB activity through PI3K/Akt pathways [268,269], and also, treatment of NB4 leukemic cells with vitamin D causes a rapid phosphorylation of IκBα [270]. Contrary to these observations, vitamin D has been shown to inhibit NF-κB activity by increasing IκBα expression in different cell lines [271–273]. Sun et al. [274], using mouse embryonic fibroblasts derived from *Vdr*–/– mice, demonstrated that VDR plays an inhibitory role in NF-κB activation by regulating IκBα levels and VDR-RELA (p65) interaction. This role for VDR was supported by a recent study that also demonstrated that 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits transcriptional activity of NF-κB in breast cancer cells via histone deacetylase (HDAC3 and SMRT)–mediated p65 transrepression [275]. Kovalenko et al. [276] showed direct transcriptional

transcription factors; GSK-3, Glycogen synthase kinase-3; HDAC, Histone deacetylase; IKK, I-κB kinase; IP3, inositol 1,4,5-trisphosphate; Mdm2, Mouse double minute 2; MEK, Raf-1-MAPK/ERK kinase; PDK1, Phosphatidylinositol-dependent kinase 1; PI3-K, Phosphatidylinositol 3 kinase; PIP2, Phosphatidylinositol (4,5)-phosphate; PIP3, Phosphatidylinositol (3,4,5) phosphate; PKC, Protein kinase C; PLC, phospholipase C; PLD, Phospholipase D; PPI1, Protein phosphatase 1-like protein; pRB, Retinoblastoma protein; PTEN, Phosphatase and tensin homolog; SHIP 1 and 2, Src homology 2 (SH2) containing phosphatases 1 and 2; SKP2, Ubiquitin ligase; DR, Vitamin D receptor.

regulation by  $1,25(\text{OH})_2\text{D}_3$  of NF- $\kappa\text{B}$  in RWPE1 immortalized but nontumorigenic prostate cells. Fekrmandi et al. [277] found that  $1,25(\text{OH})_2\text{D}_3$  suppressed NF- $\kappa\text{B}$  function by enhancing the turnover of the FBW7-dependent subunit.  $1,25(\text{OH})_2\text{D}_3$  also indirectly inhibits NF- $\kappa\text{B}$  by directly stimulating expression of IGFBP-3, an inhibitor of NF- $\kappa\text{B}$  [278].

Interestingly, in relation to NF- $\kappa\text{B}$  regulation, as early as 1994, Chen and DeLuca isolated and characterized a vitamin D-induced gene in HL-60 cells [279]. The encoded protein, named vitamin D-upregulated protein-1 (VDUP1), is a thioredoxin-binding protein-2 [280]. Thioredoxin has several roles in processes such as proliferation or apoptosis. It also promotes DNA binding of transcription factors such as NF- $\kappa\text{B}$ , AP-1, TP53, and PEBP2. In addition, overexpression of thioredoxin suppresses the degradation of I $\kappa\text{B}$  and the transactivation of NF- $\kappa\text{B}$ , whereas overexpression of nuclear-targeted thioredoxin exhibits enhancement of NF- $\kappa\text{B}$ -dependent transactivation [281]. However, it is in only more recent studies that a coupling between VDUP1 and cancer has been made. The expression of VDUP1 was found to correlate with malignant status of colorectal and gastric cancers [282]. 5-Fluorouracil, which is widely used for treatment of colon cancer, induces VDUP1 expression in the SW620 colon cancer cell line [283]. In smooth muscle cells and cardiomyocytes, VDUP1 inhibits proliferation and is involved in induction of apoptosis [284,285]. A relation with vitamin D effects on cancer is made by two recent studies showing induction of VDUP1 by  $1,25(\text{OH})_2\text{D}_3$  in tumor cells and that VDUP1 induces cell cycle arrest [286,287]. Moreover, interaction with histone deacetylase (HDAC; see Fig. 84.1) and promyelocytic leukemia zinc finger (PLZF) was demonstrated. Interestingly and further complicating the story, PLZF inhibits  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation of U937 leukemic cells by binding to the VDR and inhibiting gene transcription [288,289]. Interestingly, a new related gene, DRH1, was cloned, and its expression was found to be strongly reduced in hepatocellular carcinoma tissue compared with normal liver [290]. DRH1 is 41% homologous with VDUP1. Whether this points to a new family of cancer genes remains to be established, but it certainly opens new venues for intervening in cancer cell growth.

Important in the regulation of gene expression is the involvement of noncoding RNAs, including microRNAs (miRNAs), long non-coding (lnc) RNAs, and small nucleolar (sno) RNAs [291]. These small endogenous RNAs target mRNAs and cause translational repression or degradation [292], thereby affecting a multitude of cellular functions including all processes identified to be vitamin D targets in cancer biology. In gastric cancer cells, it was found that miR-145 is induced by  $1,25(\text{OH})_2\text{D}_3$  and mediates antiproliferative effects on

gene regulation by vitamin D, with a direct target transcription factor E2F3 [293]. Also in other cancers, vitamin D regulates miRNA expression, which opens new routes for therapeutic targeting [294,295]. Several studies have shown that VDR itself is a target for miRNAs: miR-125b repressed endogenous levels of VDR in MCF-7 cells. Since miR-125b is downregulated in cancer, this may result in upregulation of the VDR and positively influence the antitumor effects of vitamin D [296]. Also, miR-1204 and miR-214 downregulate VDR expression in breast cancer cell lines [185,297]. The regulation of miRNAs by vitamin D in cancer model systems and impact on  $1,25(\text{OH})_2\text{D}_3$  signaling is reviewed by Ma et al. [298]. Developments in the noncoding RNA field are going fast. High-throughput techniques such as qPCR arrays and whole-genome sequencing will provide a broad inventory of vitamin D regulation of noncoding RNAs [297,299]. Also, the possibilities that noncoding RNAs packaged in exosomes can (1) signal between cells and (2) may serve as diagnostic markers are important innovations [300–304]. These developments warrant an updated review on noncoding RNAs, vitamin D, and cancer. Recently, also circular (circ) RNAs have gained a growing interest due to their broad expression and potential role in cancer [305]. The circular RNA hsa\_circ\_0060927 is generated from the CYP24A1 pre-mRNA and found to be expressed in colorectal cancer tissues and to be induced by  $1,25(\text{OH})_2\text{D}_3$  [306]. This latter might not be that surprising as the CYP24A1 gene is one of the most sensitive  $1,25(\text{OH})_2\text{D}_3$  genes. However, it may add a layer of complexity in the relationship between CYP24A1 and  $1,25(\text{OH})_2\text{D}_3$  in the regulation of cancer cells once we know the function of hsa\_circ\_0060927. The role of noncoding RNAs in vitamin D signaling and function is discussed in greater detail in Chapter 14.

Several alternate therapeutic targets for vitamin D anticancer activity can be mentioned here that are discussed in more detail in the following various chapters on specific cancers. Vitamin D regulates enzymes involved in estrogen and androgen synthesis and metabolism since these pathways drive the growth of breast and prostate cancer, respectively [307–311]. Vitamin D downregulates the expression of estrogen receptor (ER) $\alpha$  (ESR1). Two negative VDREs in the ER promoter act together in inhibiting ESR1 expression by  $1,25(\text{OH})_2\text{D}_3$  [312].

Telomerase activity provides a mechanism for unlimited cell division. In HL-60 cells,  $1,25(\text{OH})_2\text{D}_3$  inhibits telomerase activity, [313] and higher circulating vitamin D levels are associated to telomere length in leukocytes [314]. Additionally, whether the homeobox genes will prove to be a major target for vitamin D action in cancer remains to be elucidated, but in a differential expression screen in the human U937 leukemic cells, the HoxA10

gene was shown to be regulated by  $1,25(\text{OH})_2\text{D}_3$  [315]. A link with miRNA was made in gastric cancer. MiRNA-99b-3p is a direct target of vitamin D and reduces HoxD3 expression. Vitamin D also reduces HoxD3 expression suggestive for a link, but no definitive proof was provided that this vitamin D effect relies on induction of miRNA-99b-3p [316]. It was further suggested that the inhibitory effects on prostate cancer cell growth by vitamin D were related to the ability of  $1,25(\text{OH})_2\text{D}_3$  to modulate assembly of CX32 (GJB1) proteins into gap junctions, a way of cell–cell communication that is important in cell growth and differentiation [317]. For effects on other cell–cell junctions, see Section 3.4 on Differentiation.

A final but very important area is the antiinflammatory activity of vitamin D. Inflammation and carcinogenesis are intimately related, and immune cells in the tumor or vicinity of the tumor are critical determinants in tumor progression/regression. The currently most successful and promising cancer therapy is based on genetically engineered immune cells; chimeric antigen receptor (CAR)-T cells [318]. Yet, no data are available on vitamin D and CAR-T cells, but a broad range of effects on immune cells have been described and will be discussed in detail in other chapters. Vitamin D inhibits many proinflammatory pathways perhaps contributing to its chemoprevention as well as its therapeutic activity [278]. Stromal–epithelial cross-talk is important in the effects of  $1,25(\text{OH})_2\text{D}_3$  on the inflammatory process, as was shown in prostate cancer [319]. Vice versa, proinflammatory cytokines such as TNF $\alpha$  and IL-6 can decrease the expression of CYP27B1 in colon cancer, impairing activation of vitamin D, so limiting its antiinflammatory action again [320] and inflammation can induce CYP24A1 translation via an internal ribosome entry site [321].

Maybe not directly considered as a classical oncogenes, an oncogenic role for CYP24A1 is suggested by data showing amplification of the *CYP24A1* locus on chromosome 20q13.2 [322], and increased copy number causing overexpression in colorectal cancer [323]. CYP24A1A1 is mentioned as a new prognostic biomarker for colorectal cancer patients [324,325]. It should be noted that *CYP24A1* is located in a region at 20q13 that is found amplified in breast and ovarian cancers and that harbors about 300 other genes [326,327].

Several studies applied whole-genome profiling of  $1,25(\text{OH})_2\text{D}_3$ -treated cancer cells and patient explants. These large-scale genome-wide expression analyses will identify vitamin D–regulated genes and noncoding RNAs. These additional findings will add to the unraveling and further understanding of the mechanism of vitamin D control of cancer cell proliferation [328–330]. An RNA profiling study revealed 523 genes that were differentially expressed in breast cancer tissue

after vitamin D treatment (compared with 127 genes in normal breast tissue). These genes were mainly involved in processes such as cellular adhesion, metabolic pathways, and tumor suppressor–like pathways. Increased expression of three of these genes, *CLMN*, *SERPINB1*, and *KLK6*, is associated to prolonged relapse [331]. Tumor heterogeneity may be at the basis of the observation that in a comparative analysis of various breast cancer cells and tumor specimens, only four genes, *CYP24A1*, *CLMN*, *EFTUD1*, and *SERPINB1* were found to be upregulated in all samples. These four and *KLK6* were confirmed to be regulated by  $1,25(\text{OH})_2\text{D}_3$  in breast cancer cell lines and clinical specimens [18,332]. For sure, these whole genome-wide approaches together with single-cell and spatiotemporal expression profiling will provide a myriad of interesting molecular data. To optimally employ these data, a precise and robust description of and linkage to phenotypic/clinical data is critical.

### 3.2 Cell cycle and DNA repair

It has now been well established that vitamin D inhibits growth of cells by interfering with the cell cycle (see Chapter 86). In a randomized clinical trial, an inverse relation of vitamin D metabolite levels and Ki67 intensity (proliferative activity) in prostate cancer tissue was found after vitamin D treatment [333]. Both in breast cancer [334] and in colon cancer, inhibition of cell proliferation via vitamin D is associated with JNK1. JNK1 interacts with the VDR and regulates its expression, influencing  $1,25(\text{OH})_2\text{D}_3$ -mediated inhibition of proliferation of cancer cells [335]. Proliferating cells progress through the cell cycle, which comprises the G<sub>0</sub>/G<sub>1</sub> phase (most differentiated, nondividing cells are in the G<sub>1</sub> phase), the S phase in which new DNA is synthesized, and the G<sub>2</sub> phase, which is followed by mitosis (M phase) whereon the cells reenter the G<sub>0</sub>/G<sub>1</sub> phase. In most of the cells studied so far, treatment with  $1,25(\text{OH})_2\text{D}_3$  and its analogs results in a blockade at a specific checkpoint, i.e., the restriction point (R), in the G<sub>1</sub> phase limiting the transition of G<sub>1</sub> to S and reducing the number of cells in S phase. Some studies also have examined the effect on the G<sub>2</sub> phase, but these results are somewhat more diverse. In general, it can be concluded that blocking the transition from the G<sub>0</sub>/G<sub>1</sub> phase to the S phase plays an important role in the growth inhibitory effect of  $1,25(\text{OH})_2\text{D}_3$ . Numerous genes and proteins have been described that participate in the regulation of the cell cycle. It is beyond the scope of this chapter to discuss in detail the regulation of all of the genes/proteins by vitamin D. In Fig. 84.1, an overview is given of the interacting genes/proteins that are involved in intracellular signaling and regulating the cell cycle. These genes and proteins are part of the

cascade of events on which vitamin D exerts its effects. The components shown to be regulated by vitamin D are indicated. Fig. 84.1 is a compilation of data, and it is important to realize that probably not all of the genes/proteins are affected by vitamin D in all tumor cells. However, in this way, one can get an overview and appreciate the broad range of effects mediated by vitamin D on intracellular signaling pathways involved in regulation of (tumor) cell growth. More details on the regulation will be discussed in more detail in various other chapters in this section of the book especially Chapter 86. Overall, cell cycle checkpoint control is an interesting therapeutic target [336] where vitamin D alone or in combination with other compounds may act.

Related to cell cycle, checkpoints in DNA damage control [337,338]. Vitamin D has been implicated to be involved in control of genomic stability [339].  $1,25(\text{OH})_2\text{D}_3$  has been reported to inhibit hepatic chromosomal aberrations and DNA strand breaks [340]. This is supported by the finding that  $1,25(\text{OH})_2\text{D}_3$  and EB1089 stimulated the expression of GADD45, which stimulates DNA repair [341] and might be coupled to release of TP53 from Mdm2 (see Fig. 84.1). Notably, a recent study has shown that supplemental vitamin D<sub>3</sub> and calcium, separately but not together, decreased the level of the DNA damage marker 8-hydroxy-2'-deoxyguanosine in normal colorectal mucosa in a randomized clinical trial [342].  $1,25(\text{OH})_2\text{D}_3$  augmented DNA repair after UV-induced damage in skin cells [115,343,344], and other studies also provided information on vitamin D and DNA repair [255,345]. Tumor samples expressing low VDR harbored a unique set of genomic alterations compared with tumor samples expressing normal VDR levels [18].

### 3.3 Apoptosis, autophagy, and energy metabolism

The blockade in the cell cycle that prevents transition into S phase may cause cells to either go into apoptosis (programmed cell death) or enter a specific differentiation pathway. It is suggested that early G<sub>1</sub> phase may be the point at which switching between cell cycle progression and induction of apoptosis occurs [346,347]. Induction of apoptosis by  $1,25(\text{OH})_2\text{D}_3$  is an orderly and characteristic sequence of biochemical, molecular, and structural changes resulting in the death of the cell [348]. Apoptosis is a mechanism by which  $1,25(\text{OH})_2\text{D}_3$  inhibits tumor cell growth and may be the explanation for the tumor suppression and reduction in tumor volume found in various in vivo animal studies (see Section 2.2 and Table 84.2).

$1,25(\text{OH})_2\text{D}_3$  has been shown to regulate expression of apoptosis genes and to induce apoptosis of cancer

cells of various origins. For example,  $1,25(\text{OH})_2\text{D}_3$  and the analog Ro 25-6760 induce a cell cycle blockade in HT-29 human colon cancer cells causing growth inhibition and induction of apoptosis [349]. The *bcl-2* oncogene decreases the rate of programmed cell death [350]. However, protection of HL-60 cells against apoptosis occurred despite downregulation of *bcl-2* gene expression [351]. In several breast cancer cell lines (MCF-7, BT-474, MDA-MB-231),  $1,25(\text{OH})_2\text{D}_3$  and the analogs KH1060 and EB1089 decreased *bcl-2* expression [264,352] and also CB1093 reduced *bcl-2* expression in MCF-7 cells related to induction of apoptosis [353]. However, only in MCF-7 cells, this change in *bcl-2* expression was accompanied by apoptosis. The apoptosis induced by  $1,25(\text{OH})_2\text{D}_3$  and the analogs EB1089 and CB1093 in MCF-7 and T47D breast cancer cells does not involve caspases or TP53 activation [354].  $1,25(\text{OH})_2\text{D}_3$  induced apoptosis in MCF-7 cells via disruption of mitochondrial function, which is associated with Bax translocation to mitochondria, cytochrome *c* release, and production of reactive oxygen species [355]. It was shown that for MCF-7 cells, calpain, a calcium-dependent cysteine protease, may take over the role of the major execution protease in apoptosis-like death induced by vitamin D and EB1089 [356].

In B cell chronic lymphocytic leukemia cells in vitro (B-CLL), the vitamin D<sub>3</sub> analog EB1089 also induces apoptosis via a TP53-independent mechanism involving p38 MAP kinase activation and suppression of ERK activity [265]. In prostate cancer, the effects of vitamin D on apoptosis of tumor cells are caspase dependent and the human VDR is a target of caspase-3, suggesting that activation of caspase-3 may limit VDR activity [357].

Effects on other apoptosis genes/proteins such as BAX and BAK have been reported [358], and microarray gene expression analyses and differential screening will also definitively reveal additional vitamin D targets involved in regulating apoptosis [330,359]. Remarkably, treatment of patients with vitamin D<sub>3</sub> and calcium increased BAK immunostaining in the interior of colonic polyps [360] without affecting BCL2 expression in the same polyps [360] or in normal colon mucosa [361]. In a squamous cell carcinoma model system, the  $1,25(\text{OH})_2\text{D}_3$  analog inecalcitol showed antitumor activity via apoptosis through the activation of the caspase 8/10–caspase 3 pathway [362].

A central role for apoptosis in the action of  $1,25(\text{OH})_2\text{D}_3$  is unclear because growth inhibition of several other breast cancer cells besides MCF-7 cells appeared to be independent of apoptosis [264]. Also, MCF-7 cells that showed growth inhibition by  $1,25(\text{OH})_2\text{D}_3$  could, after removal of the hormone, again be stimulated to grow, implying transient growth inhibition and not cell death [244]. Stable transfection of leukemic U937 cells with the wild-type TP53 tumor

suppressor gene resulted in a reduced growth rate and produced cells that can undergo either apoptosis or maturation. In these cells,  $1,25(\text{OH})_2\text{D}_3$  protects against TP53-induced apoptosis and enhances TP53-induced maturation [262]. In two independent studies with HL-60 cells,  $1,25(\text{OH})_2\text{D}_3$  was found either to protect against or to have no effects on apoptosis [351,363]. Vitamin D protection against apoptosis was also detected in human U937 leukemic cells treated with tumor necrosis factor  $\alpha$  [364]. Absence of a vitamin D effect on apoptosis might be explained by the expression of the antiapoptotic protein BAG-1 p50 isoform. This protein has been shown to bind to the VDR and block vitamin D–induced transcription [365]. Presence of additional interacting factors might also be important for the eventual effect on apoptosis as in the study with HL-60 cells where, in the presence but not the absence of 9-cis-retinoic acid,  $1,25(\text{OH})_2\text{D}_3$  did induce apoptosis [363]. Role of vitamin D interaction with other factors will be discussed in more detail in Section 4. Over the years, an increasing number of studies on vitamin D and apoptosis are reported. While most studies show an increase in apoptosis also, studies report inhibition of apoptosis. This latter may be related to the effect of vitamin D on another process: autophagy.

Autophagy is a process by which cells direct their components to the lysosome via autophagosomes for degradation, and it plays an important role in tissue homeostasis. The term autophagy originates from the 1950s when it was introduced by Christian de Duve. The Nobel Prize for Physiology or Medicine in 2016 for discoveries of the mechanisms of autophagy can be considered as an indication of the significance of this process. Autophagy has been linked to various diseases, including cancer [366,367]. The role of autophagy in cancer is not unequivocal. Both stimulation and inhibition of autophagy have been proposed in cancer therapy. Several reports show that vitamin D affects autophagy, either stimulating [368,369], or VDR-mediated prevention of prosurvival autophagy [370]. The eventual effect is thought to be tumor/cancer cell context dependent.

Apoptosis and autophagy are different but related processes. The relationship is nicely summarized by Eisenber-Lerner et al. [371]. The literal citation of their conclusion is: “The cross-talk between apoptosis and autophagy is therefore quite complex, and sometimes contradictory, but surely critical to the overall fate of the cell. Furthermore, the cross-talk is a key factor in the outcome of death-related pathologies such as cancer, its development and treatment.” The relationship and/or balance between apoptosis and autophagy can also be seen for vitamin D. Several studies report vitamin D or vitamin D analog inhibition of apoptosis together with stimulation of autophagy [372–375].

A fundamental process of cellular function is energy metabolism. In normal cells, ATP is formed by a multi-step degradation (TCA cycle) of glucose and oxidative phosphorylation, which takes place in the mitochondria and is dependent on oxygen. Cancer cells can display metabolic reprogramming and employ a phenomenon called Warburg effect/aerobic glycolysis, i.e., glucose fermentation and production of lactate independent of ambient oxygen levels. This generates less energy than mitochondrial oxidative phosphorylation, but tumor cells often compensate by increasing glucose uptake by glucose transporters [376,377]. This increased glucose uptake is at the basis of cancer imaging, FDG-PET scanning. Considering the importance of energy metabolism for cancer cell growth, it is a target for therapeutic intervention. A role for vitamin D in the control of energy metabolism is conceivable from an evolutionary perspective [378]. Vitamin D and cancer cell energy metabolism has been extensively discussed by Abu el Maaty et al. and Sheeley et al. [379,380]. Vitamin D in combination with testosterone is reported to affect the TCA cycle by regulating gene expression [381]. Vitamin D–induced decrease in expression of glucose transporter and reduction in glycolysis has been linked to decreased migration by breast cancer cells [382]. Inhibition of the Warburg effect by vitamin D has been reported in non–small-cell lung cancer [383] and colorectal cancer cells [384]. A study in colorectal cancer cells brings together the regulation of an oncogene, regulatory noncoding RNA, energy metabolism, and vitamin D. A long noncoding RNA induced by vitamin D suppresses glycolysis via enhanced degradation of cMyc [385]. However, vitamin D augmented repair of UV-induced DNA damage in skin cells is linked to an increased energy availability [344]. This indicates that the eventual cellular response, e.g., proliferation, differentiation, repair, is important to take in account.

In summary, the data obtained so far show that  $1,25(\text{OH})_2\text{D}_3$ -induced growth inhibition can be related to apoptosis in some cases, but that growth inhibition also can be observed independent of apoptosis. Possibly in these latter cases, induction of autophagy and/or differentiation is more prominent. The factor(s) that decide whether cells undergo apoptosis or go another route like differentiation is(are) unclear but is probably dependent on cell cycle stage, DNA damage, presence of other factors, and levels of expression of various oncogenes and tumor suppressor genes. These variables contribute to what appears to be cell-specific actions of vitamin D to induce apoptosis and/or autophagy. Here also the cancer cell context in the tumor (stromal and immune cells) is important for the eventual effect. An interesting phenomenon to be studied concerning vitamin D and apoptosis is calbindin 28K. Calbindin 28K is a well-known vitamin D–induced protein, which has recently

been shown to inhibit apoptosis [386]. It is tempting to speculate that calbindin 28K plays a role in the decision whether vitamin D induces cells to differentiate or to go into apoptosis or that it is involved when  $1,25(\text{OH})_2\text{D}_3$  protects against apoptosis. Additionally, EB1089 induces lysosomal changes and autophagic cell death in human MCF-7 breast cancer cells [387,388]. Finally, energy metabolism is an important target for vitamin D in cancer cells where various cellular effects of vitamin D may converge and which deserves extensive research in the future.

### 3.4 Cell differentiation

Differentiation is another cellular process in the array of vitamin D anticancer actions. There is a considerable body of evidence that human cancer cells can be suitable candidates for differentiation therapy with vitamin D [183]. However, mechanisms of  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation are cell-type and cell-context specific [389,390]. The coupling between proliferation and differentiation has been most widely studied for cells of the hematopoietic system and keratinocytes. In general,  $1,25(\text{OH})_2\text{D}_3$  inhibits proliferation and induces differentiation along the monocyte–macrophage lineage. Rapidly proliferating and poorly differentiated keratinocytes can be induced to differentiate by  $1,25(\text{OH})_2\text{D}_3$ . A further relationship between the vitamin  $\text{D}_3$  system and differentiation is demonstrated by the fact that in poorly differentiated keratinocytes,  $1,25(\text{OH})_2\text{D}_3$  production and vitamin D receptor levels are high, whereas after induction of differentiation, these levels decrease [391]. In melanoma cells, in addition to growth inhibition [84],  $1,25(\text{OH})_2\text{D}_3$  stimulates melanin production [392]. Effects on differentiation have also been reported for other cell types. Inhibition of prostate cancer cell proliferation is paralleled by an increased production of PSA per cell, a sign of differentiation [393,394]. In the BT-20 breast cancer cells,  $1,25(\text{OH})_2\text{D}_3$  induced morphological changes indicative for differentiation [395]. In triple-negative breast cancer,  $1,25(\text{OH})_2\text{D}_3$  inhibits cancer stem-like cells and induces differentiation [396]. In several breast cancer cell lines, the stimulation of differentiation has been established by determining lipid production by the cells [264]. In this study, Elstner et al. demonstrated an uncoupling between effects on proliferation and differentiation. In two breast cancer cell lines,  $1,25(\text{OH})_2\text{D}_3$  and various analogs induced differentiation even though the cells were resistant to cell cycle and antiproliferative effects. This together with data obtained with human myelogenous leukemia cells [257] suggests a dissociation between the cellular vitamin  $\text{D}_3$  pathways involved in regulation of differentiation and proliferation (see also Section 5).

For an HL-60 subclone, a similar observation was made [239], and in another HL-60 subclone, the induction of differentiation was found to precede the  $\text{G}_0/\text{G}_1$  cell cycle blockade. In contrast to the aforementioned observations on stimulation of differentiation,  $1,25(\text{OH})_2\text{D}_3$  inhibits erythroid differentiation of the erythroleukemia cell line K562 [397], and  $1,25(\text{OH})_2\text{D}_3$  inhibits activin A-induced differentiation of murine erythroleukemic F5-5 cells [398]. Paracalcitol, a vitamin  $\text{D}_2$  analog, converted committed myeloid hematopoietic stem cells from wild-type but not from VDR knockout mice to differentiate into macrophages [399]. Osteoclast-like differentiation of malignant plasma cells is enhanced by  $1,25(\text{OH})_2\text{D}_3$  [400].

Shabahang et al. [2] found that the VDR level correlated with the degree of differentiation in human colon cancer cell lines and suggested it might serve as a useful biological marker in predicting clinical outcome in patients. Differentiation of rapidly dividing HT-29 colon cancer cells to differentiated slowly proliferating cells was associated with decreased VDR abundance, loss of VDR homologous upregulation, and the development of hormone unresponsiveness to  $1,25(\text{OH})_2\text{D}_3$  [351].  $1,25(\text{OH})_2\text{D}_3$  induces an adhesive phenotype typical of the differentiated epithelial cells that is mostly based on the upregulation of E-cadherin and other plasma membrane adhesion proteins of adherens junctions ( $\alpha$ -catenin) and tight junctions (occludin, claudins, ZO-1) [243,401]. Also,  $1,25(\text{OH})_2\text{D}_3$  regulates the phenotype of human breast cancer cells. Thus, it increases the expression of E-cadherin, claudin-7, and occludin and of proteins such as paxillin, focal adhesion kinase, and  $\alpha\text{v}$ - and  $\beta 5$ -integrins that are involved in adhesion to the substratum [402]. Moreover,  $1,25(\text{OH})_2\text{D}_3$  represses several markers of the basal/myoepithelial phenotype (P-cadherin, smooth muscle  $\alpha$ -actin, and  $\alpha 6$  and  $\beta 4$ -integrins), the proinvasive and proangiogenic protein tenascin-C protein, and the mesenchymal marker N-cadherin that are associated with aggressiveness and poor prognosis in breast cancer [403,404]. The effect of vitamin D on the epithelial–mesenchymal transition can also be considered related to differentiation or in other words, retaining the differentiation status.

### 3.5 Growth factors and growth factor receptors

The interaction with tumor- or stroma-derived growth factors is important for the action of vitamin D. Stimulation of breast cancer cell proliferation by coculture with fibroblasts is inhibited by  $1,25(\text{OH})_2\text{D}_3$  [405]. A good candidate to interact with the  $1,25(\text{OH})_2\text{D}_3$  action is transforming growth factor- $\beta$  (TGF $\beta$ ). TGF $\beta$  is involved in cell cycle control and apoptosis [406,407]. TGF $\beta$  can interfere with the cascade of events in the GI

phase described before and inhibit the ability of cells to enter S phase when it is present during the G1 phase. TGF $\beta$  has been shown to suppress *c-myc*, cyclin A, cyclin E, and cdk2 and cdk4 expression [407]. In line with this, TGF $\beta$  has been reported to inhibit phosphorylation of p110<sup>RB</sup> [408]. Vitamin D<sub>3</sub> compounds induce dephosphorylation of the retinoblastoma gene product, and vitamin D<sub>3</sub> growth inhibition of MCF-7 breast cancer cells is inhibited by a TGF $\beta$  neutralizing antibody [409]. 1,25(OH)<sub>2</sub>D<sub>3</sub> and several analogs stimulated the expression of TGF $\beta$  mRNA and secretion of active and latent TGF $\beta$ 1 by the breast cancer cell line BT-20 [176]. 1,25(OH)<sub>2</sub>D<sub>3</sub> enhanced TGF $\beta$ 1 gene expression in human keratinocytes [410] and the secretion of TGF $\beta$  in murine keratinocytes [411]. In both studies, antibodies against TGF $\beta$  inhibited the growth inhibitory effect of vitamin D<sub>3</sub>.

Further evidence for a vitamin D<sub>3</sub>–TGF $\beta$  interaction is that bone matrix of vitamin D–deficient rats contains substantially less TGF $\beta$  than controls [412]. It has been shown for the interaction between TGF $\beta$  signaling pathways and vitamin D that the cross-talk may be mediated by Smad3. Smad3, one of the SMAD proteins downstream in the TGF $\beta$  signaling pathway, was found in mammalian cells to act as a coactivator specific for ligand-induced transactivation of VDR by forming a complex with a member of the steroid receptor coactivator-1 protein family in the nucleus [413]. However, Smad3 is not of itself sufficient to coactivate VDR in TGF $\beta$ /vitamin D<sub>3</sub>-resistant MCF7L cells, and other factors are required. It was found that the PI 3-kinase pathway inhibitor LY29004 inhibited the synergy of TGF $\beta$  and EB1089 on VDR-dependent transactivation activity. This indicates that the cross-talk between TGF $\beta$  and vitamin D signaling is also PI 3-kinase pathway dependent [414]. Therefore, on the basis of these consistent findings, TGF $\beta$  is a likely candidate to play a role in the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced growth inhibition [414]. Gene expression profiling of 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated normal and breast cancer cells identified enrichment of TGF $\beta$  signaling pathway [332].

Interactions with the insulin-like growth factor [266] system have also been described. IGFs are potent growth stimulators of various cells, and their effect is regulated via a series of IGF binding proteins (IGFBPs). The IGFBPs, especially IGFBP-3, have potent antiproliferative and proapoptotic actions [415]. These effects include both IGF-dependent actions, by sequestering the potent growth factor, and IGF-independent, having direct actions via its own receptor [416,417]. Among the many ways, vitamin D inhibits prostate cancer growth; stimulation of IGFBP-3 may be a major contributor [418]. 1,25(OH)<sub>2</sub>D<sub>3</sub> and the analog EB1089 inhibit the IGF-I-stimulated growth of MCF-7 breast cancer cells [419]. In prostate cancer cell lines, 1,25(OH)<sub>2</sub>D<sub>3</sub> induced

expression of IGFBP-6 but not IGFBP-4 [420]. In human osteosarcoma cell lines, 1,25(OH)<sub>2</sub>D<sub>3</sub> and the analog 1 $\alpha$ -dihydroxy-16-ene-23-yne-26,27-hexafluorocholecalciferol potently stimulated the expression and secretion of IGFBP-3 [421–423]. In one study, an association has been made between increased IGFBP-3 levels and 1,25(OH)<sub>2</sub>D<sub>3</sub> growth inhibition [421]. Recent observations that antisense oligonucleotides to IGFBP-3 prevented growth inhibition of prostate cancer cells by 1,25(OH)<sub>2</sub>D<sub>3</sub> [329] provided further evidence for an interplay between 1,25(OH)<sub>2</sub>D<sub>3</sub> and IGFBP-3. Interestingly, in the human osteosarcoma cell line, MG-63, 1,25(OH)<sub>2</sub>D<sub>3</sub> and TGF $\beta$  synergistically increased IGFBP-3 secretion [423]. A study published in 2021 underscores the interaction between 1,25(OH)<sub>2</sub>D<sub>3</sub> and TGF $\beta$  by demonstrating a synergistic stimulation of IGFBP3 expression [424]. In a randomized double-blind placebo-controlled 12-month study of 20,000 IU cholecalciferol orally per week, no differences in serum IGF-I and in IGFBP3 between vitamin D and placebo were detected [425]. Unfortunately, no data on intratumor concentrations were available, as these might be more insightful than circulating levels.

IGF-II is also a growth and survival factor for colorectal cancer cells, and 1,25(OH)<sub>2</sub>D<sub>3</sub> and several analogs interfere with IGF-II signaling. They upregulate IGFBP-6, which inhibits IGF-II signaling, and type II IGF receptor (IGF-R-II) that also blocks this pathway and accelerates IGF-II degradation [426,427]. An example of growth factor receptor regulation by 1,25(OH)<sub>2</sub>D<sub>3</sub> concerns the epidermal growth factor receptor (EGFR). This receptor is downregulated in T47-D breast cancer cells and upregulated in BT-20 breast cancer cells. Nevertheless, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits the growth of both cell lines [428,429]. The 1,25(OH)<sub>2</sub>D<sub>3</sub> growth inhibition was strongest in lung cancer cells with a mutated EGFR [430]. These data provide evidence that interactions with growth factors are part of the 1,25(OH)<sub>2</sub>D<sub>3</sub> action on tumor cells. In primary colon adenocarcinoma cells as well as in the colon cancer Caco-2 cell line, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits EGF mitogenic signaling, and a mutual modulation of receptor expression between 1,25(OH)<sub>2</sub>D<sub>3</sub> and EGF has been proposed [431,432]. In A431 epidermoid cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> alters EGFR membrane trafficking and inhibits EGFR signaling [433].

It was found that TCF-4, a transcriptional regulator and beta-catenin binding partner, is an indirect target of the VDR pathway. TCF-4 functions as a transcriptional repressor that restricts breast and colorectal cancer cell growth. 1,25(OH)<sub>2</sub>D<sub>3</sub> increases TCF-4 at the RNA and protein levels in several human colorectal cancer cell lines, which is completely dependent on the VDR. This 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR-mediated increase in TCF-4 may have a protective role in colon cancer as well as other diseases [434]. In ovarian cancer,

1,25(OH)<sub>2</sub>D<sub>3</sub> decreases the expression of lncRNA CCAT2, and by blocking the CCAT2–TCF-4 interaction, it reduces c-Myc expression and inhibits the binding to TCF-4, which is paralleled by a decrease in growth and migration [435]. In an *in vivo* model of liver tumor formation, vitamin D deprivation caused tumor growth in the context of TGFβ/Smad3 disruption, via regulation of Toll-like receptor 7 expression and β-catenin activation [436].

As described before, it is clear that 1,25(OH)<sub>2</sub>D<sub>3</sub> has effects on the transcription of numerous RNA species, including coding and noncoding RNAs, and multiple interactions with various growth factors exist. With respect to growth inhibition, at this time, two models of action can be postulated. In the first one, 1,25(OH)<sub>2</sub>D<sub>3</sub> directly interferes with a crucial gene(s) involved in the control of the cell cycle. In this case, in view of the general pattern of the genes involved in cell cycle control, this mechanism of action will be similar in all types of cancer cells. However, the effect on cell cycle genes will be dependent on contextual parameters such as tumor stroma, immunological makeup, and thereby the presence or absence of additional growth factors and cytokines. This will eventually determine the differences in 1,25(OH)<sub>2</sub>D<sub>3</sub> action between cancer types of different origin but also within cancer types of similar origin. In the second model, 1,25(OH)<sub>2</sub>D<sub>3</sub> may regulate cell cycle indirectly via changing the production of regulatory and signaling molecules such as growth factors, growth factor signaling, growth factor–binding protein levels, or receptor regulation. It is conceivable that a combination of both models forms the basis of 1,25(OH)<sub>2</sub>D<sub>3</sub> regulation of tumor cell growth. It is conceivable that the consequences, e.g., apoptosis, autophagy, differentiation, of cell cycle interference are dependent on the mutational profile of the cancer cell and the tumor microenvironment. A complicating aspect herein is the tumor heterogeneity [15,16].

#### 4. Combination therapy

The data obtained with 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs on growth inhibition and stimulation of differentiation offer promise for their use as an anticancer treatment. Single agent treatment with low calcemic 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs could be useful; however, combination therapy with other tumor effective drugs may provide an even more beneficial effect [156]. More and more studies are focusing on combination therapies with 1,25(OH)<sub>2</sub>D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs.

Initially, most combination studies focused on breast cancer cells and the combination of one of the most widely used endocrine therapies, the antiestrogen tamoxifen, with 1,25(OH)<sub>2</sub>D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs.

This combination resulted in a greater growth inhibition of MCF-7 and ZR-75-1 cells than treatment with either compound alone [132,437]. In combination with tamoxifen, the cells were more sensitive to the antiproliferative action of 1,25(OH)<sub>2</sub>D<sub>3</sub> and the analogs; that is, the EC<sub>50</sub> values of the vitamin D<sub>3</sub> compounds in the presence of tamoxifen were lower than those in the absence of tamoxifen [244]. Vitamin D induces tamoxifen sensitivity in MCF-7 cells via inhibition of Wnt signaling. Studies with MCF-7 cells suggested a synergistic effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> and tamoxifen on apoptosis [438]. In addition, in *in vivo* breast cancer models, a synergistic effect of the tamoxifen-1,25(OH)<sub>2</sub>D<sub>3</sub> analogs combination was observed [132,133].

Another interesting interaction relevant to breast cancer is that vitamin D inhibits aromatase, thus reducing the estrogenic stimulus for proliferation [311]. Combination of 1,25(OH)<sub>2</sub>D<sub>3</sub> and aromatase inhibitors also showed synergistic activity in breast cancer cells. 1,25(OH)<sub>2</sub>D<sub>3</sub> also downregulates the estrogen receptor, again reducing the ability of estrogens to stimulate breast cancer growth [439]. Additional data on the interaction between the estrogen/antiestrogen system and vitamin D come from studies showing the presence of an estrogen-responsive element in the VDR promoter and regulation of VDR by estradiol in breast cancer cells [440]. It is intriguing that the stimulator of breast cancer cell growth induces the expression of the receptor for a growth inhibitor. VDR upregulation in breast cancer cells and increased transcriptional activity was mimicked by the phytoestrogens resveratrol and genistein and blocked by tamoxifen [441]. Interaction between the estrogen system and CYP24A1 is also of importance. Data have shown that genistein inhibits CYP24A1 activity in prostate cancer cells and thereby increases the responsiveness to 1,25(OH)<sub>2</sub>D<sub>3</sub> [442,443]. The combination of genistein and cholecalciferol has been tested in a phase II randomized placebo-control trial for prostate cancer, but the results were inconclusive [444].

Estradiol induces metastasis-associated protein (MTA)-3, a component of the Mi-2/NuRD transcriptional corepressor complex that inhibits Snail1, which is in turn a repressor of VDR gene expression [445,446]. In this way, estradiol may increase VDR levels in breast cells. In colon cancer also, VDR upregulation by estradiol has been reported; however, in colon, it was hypothesized to contribute to the protective effect of estradiol on chemically induced colon carcinogenesis [447]. These interactions between the vitamin D and estrogen endocrine systems in the regulation of cancer [310] are promising and warrant further detailed analyses, e.g., regarding tissue (cancer)-specific effects. Interaction with another sex steroid, testosterone, has been described for ovarian cancer. Vitamin D inhibits

dihydrotestosterone (not convertible to estradiol) growth stimulation of ovarian cancer cells [448]. Intriguingly, also here the growth stimulator and growth inhibitor mutually upregulate their receptors. Triple-negative breast cancer can be targeted with androgen receptor (AR) and/or VDR agonists to reduce viability of cancer cells and to change in cancer stem cell phenotype. The combination of AR and VDR agonists with chemotherapy was additive [449]. In prostate cancer cells, it has been shown that  $1,25(\text{OH})_2\text{D}_3$  while inhibiting androgen stimulated growth upregulates the androgen receptor [450].

Interaction with another steroid in regulating cancer cells has already been reported in 1983. The synthetic glucocorticoid dexamethasone and  $1,25(\text{OH})_2\text{D}_3$  synergistically induced differentiation of murine myeloid leukemia cells [451]. This was supported by in vitro and in vivo data that dexamethasone enhanced the effect of vitamin D on growth inhibition, cell cycle arrest, and apoptosis of squamous carcinoma cells [452,453]. A possible mechanism is the upregulation of VDR by dexamethasone [452]. An interesting aspect of this combination is not only the direct interaction at cancer cell level but also in the control of the calcemic action of  $1,25(\text{OH})_2\text{D}_3$ . Glucocorticoids inhibit intestinal calcium absorption and increase renal calcium excretion, and in this way, it may limit the hypercalcemic action of  $1,25(\text{OH})_2\text{D}_3$  [454].

Combinations of vitamin D and retinoids have been examined in various systems. A combination of retinoic acid and  $1,25(\text{OH})_2\text{D}_3$  resulted in a more profound growth inhibition of both T47-D breast cancer cells [455] and LA-N-5 human neuroblastoma cells [456]. 9-cis-Retinoic acid augmented  $1,25(\text{OH})_2\text{D}_3$ -induced growth inhibition and differentiation of HL-60 cells [457]. Besides growth inhibition and differentiation effects, the combination of  $1,25(\text{OH})_2\text{D}_3$  and various isomers of retinoic acid was more potent in reducing angiogenesis than either compound alone [167,458,459]. The background of the interaction between retinoids and  $1,25(\text{OH})_2\text{D}_3$  may be attributed to heterodimer formation of their respective receptors [460].

For several cytokines, interactions with  $1,25(\text{OH})_2\text{D}_3$  have been described, stressing the importance of immune system and vitamin D relationship in cancer [461,462]. Interferon- $\gamma$  and  $1,25(\text{OH})_2\text{D}_3$  synergistically inhibited the proliferation and stimulated the differentiation of myeloid leukemia cells [463]. Treatment of LLC-LN7 tumor cells with  $1,25(\text{OH})_2\text{D}_3$  and IFN- $\gamma$  synergistically reduced tumor granulocyte-macrophage colony-stimulating factor (GM-CSF) secretion and a blockage in the capacity of the tumor cells to induce granulocyte-macrophage-suppressor cells [103]. In the mouse myeloid leukemia cells,

interleukin-4 enhanced  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation [464]. Also with interleukin-1 $\beta$ , interleukin-3, interleukin-6, and interleukin-12, interactions with  $1,25(\text{OH})_2\text{D}_3$  have been reported [465–467]. Although a small sample size (43 cases vs. 86 controls), in clear cell renal cell carcinoma patients but not in controls serum, interleukin-6 and  $25(\text{OH})\text{D}$  levels were inversely correlated. pSTAT3 signal was significantly higher in cancerous tissue from  $25(\text{OH})\text{D}$ -deficient (<20 mg/mL) than in  $25(\text{OH})\text{D}$ -insufficient and  $25(\text{OH})\text{D}$ -sufficient groups (>20 mg/mL) [468].  $1,25(\text{OH})_2\text{D}_3$  and tumor necrosis factor synergistically induced growth inhibition and differentiation of HL-60 [469]. For MCF-7 cells, an interaction between  $1,25(\text{OH})_2\text{D}_3$  and tumor necrosis factor has also been reported [467,470]. In the presence of GM-CSF, lower concentrations of  $1,25(\text{OH})_2\text{D}_3$  could be used to achieve a similar antiproliferative effect in MCF-7 cells [471] and to induce differentiation of U937 myeloid leukemic cells [472].

Recently, interactions with a plant-derived polyphenolic antioxidant, carnosic acid, were demonstrated in the differentiation of HL-60 cells, which was related to a decrease in the intracellular levels of reactive oxygen species [473,474].  $1,25(\text{OH})_2\text{D}_2$  in combination with a plant polyphenol is a potent inducer of differentiation in acute myeloid leukemia cells [475]. Other factors shown to interact with  $1,25(\text{OH})_2\text{D}_3$  are butyrate [476,477], melatonin [478], and other factors, such as EGFR, described in Section 3.5. The EGFR signals via the tyrosine kinase pathway. Vitamin D enhances the effect of tyrosine kinase inhibitors [479] also in a triple combination with cytostatic drugs [480]. The relationship between vitamin D and LXR [21] requires further studies as the combination of vitamin D and LXR ligand T0901317 is more potent in inducing apoptosis in breast cancer cells [481].

The so far described studies are combination of vitamin D with other hormones and/or bioactive compounds (growth factors and cytokines) where the mechanism of combination may lie in convergence and interaction of their respective signaling pathways and can be primarily cancer cell specific. Interestingly, also for two other, broadly used cancer therapies interactions with vitamin D have been observed: first, the combination of chemotherapy/cytostatic drugs and vitamin D. In vivo adriamycin and in vitro carboplatin, cisplatin, and doxorubicin interacted synergistically with  $1,25(\text{OH})_2\text{D}_3$  to inhibit breast cancer cell growth [127,482–484]. In a carcinogen-induced rat mammary tumor model, treatment with  $1\alpha-(\text{OH})\text{D}_3$  and 5-fluorouracil, however, did not result in enhanced antitumor effects [100]. In other cancer types, enhancement of chemotherapy has been described [485–488]. Unwanted side effects are often seen with the use of cytostatics. Vitamin D together

with pirfenidone limits chemotherapy induced renal toxicity in mice [489].

Secondly, the combination of vitamin D and radiotherapy is under investigation. Vitamin D enhances the effect of radiation therapy in various cancer cell types [490–494]. A combination of vitamin D with photodynamic therapy to enhance tumor cell death has also been reported [495,496].

Combination studies showed that vitamin D is sensitizer for proton therapy [497] and cryoablation [498–500]. The mechanism(s) by which vitamin D enhances or sensitizes these chemotherapy and radiotherapy are generally unknown, but it may involve effects on the immune system. Two studies on combination with radiotherapy point in this direction [501,502].

It is known that food components can impact the efficacy of cancer therapies. For example, the herb curcumin negatively affects the pharmacokinetics of tamoxifen [503] while the acid beverage cola positively affects the pharmacokinetics of erlotinib by increasing the bioavailability [504]. For vitamin D also, interaction with food components curcumin [505,506] and S-adenosylmethionine has been reported. Intake of food or beverage components may impact vitamin D metabolism. Chronic intake of ethanol regulates CYP27B1 and CYP24A1 in a breast cancer mouse model [507].

A development over the recent years is a novel way of delivery of vitamin D in combination with other compounds. Vitamin D is applied together with cisplatin, paclitaxel, doxorubicin, or etoposide in nanoparticles or micelles [508–511]. Also micelles have been generated that both in vitro and in vivo targetedly delivered high dosages of vitamin D at breast cancer cells and caused growth and metastasis inhibition [512].

The data on combinations of  $1,25(\text{OH})_2\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  analogs with various other anticancer compounds and therapies are promising and merit further analyses. The development of effective combination therapies may result in better response rates and lower required dosages, thereby reducing the risk of negative side effects. An additional benefit is that some direct actions of  $1,25(\text{OH})_2\text{D}_3$  may reduce side effects of toxic chemotherapy drugs when given in combination [513]. An overview and possibilities of combined cancer treatments of vitamin D and other compounds is given by Gocek and Studzinski [514]. The development of novel tools of drug delivery opens novel avenues for combination and targeted therapies.

## 5. Resistance and vitamin D metabolism

We will discuss first vitamin D resistance of tumor cells and second more general development of therapy resistance of tumors and cancer cells. Classic vitamin

D resistance concerns the disease hereditary vitamin D-resistant rickets, which is characterized by the presence of a nonfunctional VDR and consequently aberrations in calcium and bone metabolism (see Chapter 68). For cancer cells, the presence of a functional VDR is a prerequisite for a growth regulatory response, and a relationship between VDR level and growth inhibition has been suggested for osteosarcoma, colon carcinoma, breast cancer, prostate cancer cells, and rat glioma [263,515–518]. Cell lines established from DMBA-induced breast tumors in VDR knockout mice are insensitive to growth arrest and apoptosis by  $1,25(\text{OH})_2\text{D}_3$ , EB1089, and CB1093 [519]. Albeit that VDR is a prerequisite for tumor cell growth regulation, the presence of the VDR is not always coupled to a growth inhibitory response of  $1,25(\text{OH})_2\text{D}_3$ . Results from studies with transformed fibroblasts [246], myelogenous leukemia cells [239,257,520], transformed keratinocytes [521], and various breast cancer cell lines [264,522] demonstrated a lack of growth inhibition by  $1,25(\text{OH})_2\text{D}_3$  even in the presence of VDR. In this situation, the designation “resistant” is based on the lack of growth inhibition, even though, as discussed earlier in Section 3.4, some of these cells are still capable of being induced to differentiate [257,264]. This points to a specific defect in the growth inhibitory pathway. In the resistant MCF-7 cells, this defect is not located at a very common site in the growth inhibitory pathway of the cell, because the growth could still be inhibited with the antiestrogen tamoxifen [522]. For myelogenous leukemia cells, similar observations have been made [523]. Human VDR gene is transcriptionally repressed by SNAIL1 and SNAIL2/SLUG in human colon cancer cells, leading to decreased levels of VDR RNA and protein and unresponsiveness to  $1,25(\text{OH})_2\text{D}_3$  effects [524–526]. SNAIL1 causes also a decrease in VDR RNA stability [524]. Also, Snail1 represses VDR in mouse osteoblasts and SNAIL2/SLUG in human breast cancer cells [527]. In addition, Snail1 is probably mediating the decrease in VDR mRNA stability induced by oncogenic Ha-ras in mouse NIH-3T3 cells [528,529]. Treatment of HT-29 colonic carcinoma cells with the flavonolignan silibinin reduced SNAIL expression and restored VDR transcription and  $1,25(\text{OH})_2\text{D}_3$  growth inhibition [530]. Hypermethylation of about 700 base pairs upstream as well as close to the transcription start site of the VDR gene has been demonstrated and linked to reduced VDR expression and VDRE containing genes such C/EBP and p21 [531]. In cancerous tissue, the frequency of VDR promoter methylation was about four times higher than in normal tissue, and methylation status was significantly associated with tumor staging [532].

For VDR-independent resistance to growth inhibition and in general to  $1,25(\text{OH})_2\text{D}_3$  effects, several underlying mechanism(s) have been proposed, such as (1)

increased levels of VDR corepressors, (2) reduced bioavailability of  $1,25(\text{OH})_2\text{D}_3$  due to CYP24A1 upregulation and/or CYP27B1 downregulation, and increased 24-hydroxylase or decreased 25-hydroxyvitamin D3  $1\alpha$ -hydroxylase activity, respectively, and (3) disruption or phosphorylation of VDR-RXR dimers. Resistance to  $1,25(\text{OH})_2\text{D}_3$  in breast and prostate cancer cells has also been found to be a consequence of increased levels of the VDR corepressors NCoR or SMRT [533,534]. This is in line with the reported synergistic effect on the proliferation of prostate cancer cells of combined treatment with  $1,25(\text{OH})_2\text{D}_3$  and the histone deacetylase inhibitor trichostatin [476].

For the resistant MCF-7 clone, this is not related to upregulation of the P-glycoprotein [522]. Interestingly, these vitamin D-resistant MCF-7 clones can be sensitized to vitamin D by activation of protein kinase C, resulting in induction of apoptosis and transcriptional activation, suggesting that alterations in phosphorylation may affect vitamin D sensitivity [535]. Hansen et al. [536] described an interesting growth inhibition-resistant MCF-7 cell clone. This clone was not growth-inhibited, while VDR was still present and CYP24A1 could still be induced.

In the resistant leukemia JMMD3 cell line, altered regulation and DNA binding activity of *junD* as part of the AP-1 complex has been reported [252]. Resistance to growth inhibition in the presence of VDR has also been linked to disruption of the VDR-RXR complex [537] and increased RXR degradation [538]. In addition, other factors, such as the acute myeloid leukemia translocation products (e.g., PLZF), may contribute to resistance to vitamin D by sequestering the VDR [288,289]. More recently, it was shown that altered corepressor and coactivator interaction with VDR and that epigenetic preferential suppression of antiproliferative gene promoters can explain the resistance to growth inhibition [539]. Resistance has also been linked to epigenetic changes in the VDR promoter, leading to suppressed or absent expression of VDR.

A unique mechanism for vitamin D resistance in immortalized cells has very recently been uncovered. Epstein-Barr virus (EBV) has been used to transform and immortalize lymphoblasts that can grow as cell lines in vitro. EBNA3 is an EBV encoded protein that can regulate transcription of cellular and viral genes. EBNA3 binds the VDR and blocks the activation of VDR-dependent genes and protects transformed cell lines against  $1,25(\text{OH})_2\text{D}_3$ -induced growth arrest and/or apoptosis [540]. The  $1,25(\text{OH})_2\text{D}_3$ -sensitive and resistant cell clones provide interesting models to examine the molecular mechanisms of  $1,25(\text{OH})_2\text{D}_3$ -induced growth inhibition. For example, lack of p21 results in no cell cycle block [541], and no apoptosis was detected with a mutated TP53 [264]. The identification of cellular

proteins that are involved in the vitamin D resistance in new world primates might add to the understanding of tumor cell resistance to vitamin D [542,543].

An important mechanism for vitamin D resistance or reduced sensitivity in VDR containing tumor and cancer cells is  $1,25(\text{OH})_2\text{D}_3$  catabolism via the C24-hydroxylation pathway. An inverse relationship between cellular metabolism of  $1,25(\text{OH})_2\text{D}_3$  via 24-hydroxylation and growth inhibition of prostate cancer cells has been suggested [516]. The latter observation is intriguing, the more so as an inverse relationship between VDR level and induction of CYP24A1 activity was reported. In general, there is a direct relationship between VDR level and induction of CYP24A1 activity [517,544].

A role for CYP24A1 in the control of  $1,25(\text{OH})_2\text{D}_3$  action on cancer cells was provided by studies with the  $1,25(\text{OH})_2\text{D}_3$ -resistant prostate cancer cell line DU145. It was shown that  $1,25(\text{OH})_2\text{D}_3$  did inhibit the growth of these cells when it was combined with the 24-hydroxylase inhibitor Liazorole [545].  $1,25(\text{OH})_2\text{D}_3$  activity was likewise enhanced by combination with ketoconazole, a drug commonly used to treat prostate cancer that inhibits CYP24A1 activity [546,547]. Inhibition of CYP24A1 activity in HL-60 cells also altered the effect of  $1,25(\text{OH})_2\text{D}_3$  and 20-epi analogs [548]. CYP24A1-mediated reduction in  $1,25(\text{OH})_2\text{D}_3$  stimulated self-renewal of stem cell-like glioma cells [549]. Recently, epigenetic silencing of the CYP24A1 gene modulates the growth response of tumor-derived endothelial cells [550]. Selective removal of CYP24A1 in mouse mammary epithelium increases vitamin D sensitivity and reduces proliferation [551], and breast cancer growth is stimulated by CYP24A1-induced vitamin D deficiency [552]. The action of the analog EB1089 was also limited by hydroxylation at the C24 position [553]. However, it was suggested that the increased potency of EB1089 is at least partly due to resistance to CYP24A1 [328]. Alternatively, 24-hydroxylation of the analog KH1060 has been implicated as one of the mechanisms to explain the potency of this analog. The 24-hydroxylated metabolites of this analog are very stable and remain biologically active [554,555]. It has been shown that the naturally occurring 24-hydroxylated metabolite of vitamin D ( $24\text{R},25-(\text{OH})_2\text{D}_3$ ) also has a preventive effect on chemically induced colon cancer [556].

In contrast to degradation of  $1,25(\text{OH})_2\text{D}_3$  by CYP24A1 in cancer cells, recently it has become clear that tumor cells contain CYP27B1 activity and thereby are able to locally generate  $1,25(\text{OH})_2\text{D}_3$ . Expression of  $1\alpha$ -hydroxylase has been demonstrated in colorectal cancer [557]. It was postulated that in early stages, tumor cells respond by upregulating  $1\alpha$ -hydroxylase activity to counteract neoplastic growth, while at later stages of tumor development, this is lost [557]. Also in prostate

cancer [558] and inflammatory myofibroblastic tumor [559], CYP27B1 has been detected, albeit that in the latter case, the tumor contains large numbers of macrophages. Intratumoral production of  $1,25(\text{OH})_2\text{D}_3$  by CYP27B1 delays breast cancer progression in a mouse model [560]. Over the years, it has become clear that VDR but also CYP27B1, CYP24A1, and vitamin D metabolism in the tumor (cancer cells and tumor stroma including immune cells) are important determinants of the vitamin D anticancer effects. An overview of the signaling pathways of vitamin D in cancer and their role in therapeutic involvement is shown by Deep et al. [561]; a review of molecular mechanisms underlying the positive effects of vitamin D in cancer is given by Fleet et al. [562].

HL60 cells that have been cultured for 4 years in the presence of  $1,25(\text{OH})_2\text{D}_3$  became vitamin D resistant. This resulted in clones that are resistant to differentiation induction and growth inhibition. They became not only resistant to vitamin D but also to 5-beta-D-arabino-cytosine suggesting a common metabolic pathway being responsible [563]. Whether this relates to the upregulation of the multidrug resistance proteins is not clear. Development of therapy resistance is a common phenomenon. Recurrent tumors are often resistant to therapy. Adding to the complexity of this phenomenon is the presence of a specific subset of cancer cells: the cancer stem cells. These cells are highly resistant to therapies and effective in repopulating the tumor [564]. Mammospheres isolated from breast cancer cell lines showed suppressed VDR signaling, but combined treatment with  $1,25(\text{OH})_2\text{D}_3$  and a nitric oxide (NO)-donor caused a significant decrease in mammosphere size and smaller tumor volume in nude mice [565]. Inhibition of breast cancer stem cell spheroid formation by  $1,25(\text{OH})_2\text{D}_3$  was also found by Jeong et al. [566]. Effects of vitamin D on prostate progenitor/stem cells resulted in cell cycle arrest, senescence, and differentiation, which was mediated by IL-1 $\alpha$  [567]. These strategies may lead the way to find new concepts to overcome therapy resistance. Targeting cancer stem cells by vitamin D is reviewed by So and Suh [568]. Currently, numerous studies focus on the effect of vitamin D on cancer stem cells or stem-like cells. The resistance to therapeutic drugs is due to the expression of multidrug-resistant proteins on the cell membrane. ATP-dependent transporters (ATP-binding cassette (ABC) transporters) can make cancer cells multidrug resistant [569,570]. Reversal of cancer drug resistance is a potential target for vitamin D [571,572]. As the ABC transporters require energy (ATP) to transport drugs, it is conceivable that vitamin D may affect this process as it has been shown that vitamin D regulates energy metabolism in cancer cells [380]. However, yet there are limited studies on vitamin D and multidrug resistance. A study showed vitamin D effects alone and in

combination with curcumin on multidrug resistance protein 1 (ABCB1) expression and paclitaxel sensitivity in MCF-7 breast cancer cells [573]. Further studies are absolutely required to investigate vitamin D and multidrug resistance.

## 6. Stimulation of proliferation

Over the years, a limited number of studies have demonstrated that, in contrast to growth inhibition,  $1,25(\text{OH})_2\text{D}_3$  can also stimulate tumor cell growth and tumor development. In several cells,  $1,25(\text{OH})_2\text{D}_3$  has been reported to have a biphasic effect, that is, at lower concentrations ( $<10^{-9}$  M), it stimulates proliferation, and at higher concentrations ( $10^{-9}$  to  $10^{-7}$  M), it inhibits proliferation. However, growth stimulation can sometimes be observed not only at low concentrations but also at the concentrations generally found to inhibit tumor cell proliferation and tumor development.  $1,25(\text{OH})_2\text{D}_3$  has been shown to stimulate the growth of a human medullary thyroid carcinoma cell line [574]. Not only cancer cells but also several normal cells, for example, human monocytes [575], smooth muscle cells [576], endothelial cells [506], and alveolar type II cells [577], are stimulated to grow by  $1,25(\text{OH})_2\text{D}_3$ . Skin is another organ in which different effects of  $1,25(\text{OH})_2\text{D}_3$  have been observed. In vivo studies demonstrated that  $1,25(\text{OH})_2\text{D}_3$  and analogs stimulate keratinocyte proliferation in normal mice [578–581] and enhance anchorage-independent growth of preneoplastic epidermal cells [582]. In contrast, other studies showed  $1,25(\text{OH})_2\text{D}_3$  inhibition of proliferation of mouse and human keratinocytes [583,584], and  $1,25(\text{OH})_2\text{D}_3$  is also effective in the treatment of the hyperproliferative disorder psoriasis [585]. Moreover, in vivo studies demonstrated that, depending on the carcinogen,  $1,25(\text{OH})_2\text{D}_3$  can either reduce [92] or enhance the induction and development of skin tumors in mice [586,587]. In addition,  $1,25(\text{OH})_2\text{D}_3$  enhances the chemically induced transformation of BALB 3T3 cells and hamster embryo cells [588,589].  $1,25(\text{OH})_2\text{D}_3$  also enhanced 12-O-tetradecanoylphorbol-13-acetate-induced tumorigenic transformation of mouse epidermal JB6 Cl41.5a cells [590,591]. Recently, in the model of the 4T1 mouse mammary gland cancer transplanted subcutaneously, Cao et al. have shown that vitamin D stimulated the growth of primary tumors and decreased survival time of mice. The authors correlated this unfavorable effect with decreased Th1 response and increased recruitment of myeloid-derived suppressor cells [592]. A complex relation between vitamin D and proliferation was observed in colorectal cancer cells and squalene epoxidase (SQLE), one of the rate-limiting steps in cholesterol biosynthesis.

SQLE stimulates cancer cell proliferation via a combination of  $1,25(\text{OH})_2\text{D}_3$  accumulation and increased CYP24A1 expression. The authors conclude that  $1,25(\text{OH})_2\text{D}_3$  is more essential than cholesterol in stimulating cancer cell growth [593]. Although further studies are needed to fully grasp this observation by He et al. [380] it further links  $1,25(\text{OH})_2\text{D}_3$  to cancer cell energy metabolism.

Another example on stimulation of proliferation comes from research on osteosarcoma cells. In 1986, it was shown that  $1,25(\text{OH})_2\text{D}_3$  stimulated the growth of tumors in athymic mice inoculated with the ROS 17/2.8 osteosarcoma cell line [594]. Earlier the same group reported growth stimulation in vitro of these osteosarcoma cells at low concentrations but growth inhibition by  $10^{-8}$  M [515]. They speculated that this discrepancy resulted from limited in vivo availability of  $1,25(\text{OH})_2\text{D}_3$  for the tumor cells, resulting in concentrations shown to be growth stimulatory in vitro. However, in other experiments with nude mice, the availability of  $1,25(\text{OH})_2\text{D}_3$  did not seem to be a factor, as growth inhibition was observed (see Table 84.2). In particular, in nude mice implanted with human osteosarcoma cells (MG-63), growth inhibition and tumor suppression by  $1,25(\text{OH})_2\text{D}_3$  were observed [102]. In two different in vitro studies, growth inhibition of MG-63 and growth stimulation of ROS 17/2.8 cells was reported [595,596]. For smooth muscle cells, it has been demonstrated, for example, that growth inhibition or stimulation can depend on the presence of additional growth factors in the culture medium [576]. We followed up on this concept by comparing the effects of  $1,25(\text{OH})_2\text{D}_3$  and analogs on the growth and osteoblastic characteristics of the two osteosarcoma cell lines under identical culture conditions. At concentrations  $10^{-10}$  to  $10^{-7}$  M  $1,25(\text{OH})_2\text{D}_3$  caused an increase in cell proliferation by 100% in ROS 17/2.8 cells, whereas the proliferation of MG-63 cells was inhibited (Fig. 84.2) [249]. In contrast, in both cell lines,  $1,25(\text{OH})_2\text{D}_3$  stimulated osteoblast differentiation characteristics such as alkaline phosphatase activity and production of osteocalcin [249,595]. Analyses with another steroid hormone demonstrated that glucocorticoids inhibited the growth of both osteosarcoma cell lines [597,598]. These data indicate specific differences between these cell lines, especially with respect to the  $1,25(\text{OH})_2\text{D}_3$  growth regulatory mechanisms.

In addition to these biological data in cells, an epidemiological study also showed an increased risk of aggressive prostate cancer with higher levels of 25-hydroxyvitamin D<sub>3</sub> [61]. A metaanalysis by Xu et al. [599] reported a positive association between high levels of 25(OH)D<sub>3</sub> and prostate cancer. Although the authors mention several justified limitations of their study, together with the data on growth stimulation and tumor development (although detected in only a small

**FIGURE 84.2** Effect of  $1,25(\text{OH})_2\text{D}_3$  on proliferation of the osteosarcoma cell lines ROS 17/2.8 and MG-63. Effects on proliferation were examined as described by van den Bemd et al. [249].

minority of cancer cells), it demonstrates that treatment with  $1,25(\text{OH})_2\text{D}_3$  or analogs may not always cause growth inhibition and tumor size reduction. It is therefore of utmost importance to identify the mechanism(s) by which  $1,25(\text{OH})_2\text{D}_3$  exerts its inhibitory and stimulatory effects on cell growth and what the contextual conditions are when  $1,25(\text{OH})_2\text{D}_3$  stimulates cancer cell growth. This may provide tools to assess whether treatment of a particular tumor will be beneficial. The observations on growth inhibition and stimulation may also be related to tumor heterogeneity.

## 7. Conclusions

The data obtained so far, on (1) the distribution of the VDR in a broad range of tumors and (2) the inhibition of cancer cell growth, angiogenesis, metastasis, inflammation, and PTHrP synthesis as well as the stimulation of differentiation and apoptosis by  $1,25(\text{OH})_2\text{D}_3$  all hold promise for the development of treatment strategies based on vitamin D use in a wide range of cancers. Moreover, combination of vitamin D with other anti-tumor drugs, hormones, or growth factors is an important additional therapeutic option. Throughout the previous decade, data have accumulated on the cellular targets and mechanisms of action of  $1,25(\text{OH})_2\text{D}_3$ -induced cancer growth inhibition. The clinical application is enhanced by the development of  $1,25(\text{OH})_2\text{D}_3$  analogs with potent growth inhibitory actions and reduced hypercalcemic activity. Nevertheless, it is crucial for the coming years to deliver strong clinical trials to support the potential of vitamin D in cancer treatment uncovered by investigation of cultured cells, animal models, and epidemiological studies. In the

meantime, continuing research to understand the mechanisms by which vitamin D<sub>3</sub> exerts its effects on tumor cell growth is needed so that therapeutic modalities may be employed more effectively.

Finally, yet most data on vitamin D and effects on cancer cells are described based on a broad variety of tumor cell models. These are mainly described on basis of origin of the tumor, e.g., breast, prostate, lung, etc. Overall, vitamin D effects on general processes such as proliferation, differentiation, and cell death/apoptosis are described with a broad variety and some contradictory effects at the molecular level regarding impact on or involvement of specific genes. To take a next step in the molecular studies on vitamin D mechanism of action in cancer efforts should be made to classify the cellular/tumor models on basis of their underlying mutational profile, process of tumorigenesis, and the clinical phenotype. Studying the effect(s) of vitamin D against the backdrop of this knowledge will provide more robust insights into the vitamin D action in cancer and may improve the design of clinical studies.

## 8. Summary points

- There is a wealth of preclinical data demonstrating inhibition of tumor cell growth by vitamin D, vitamin D metabolites, and a range of vitamin D analogs supporting epidemiological association studies.
- Vitamin D impacts a broad range of well-known molecular targets in cancer cell biology, cell proliferation, and cell death, thereby providing a mechanistic basis for the observed cancer cell growth effects.
- Clinical studies are not unambiguously providing evidence for a therapeutic role of vitamin D in cancer.
- Vitamin D may act as an accelerator/facilitator of other anticancer drugs (combination therapies) and/or have a more preventive role (DNA repair, apoptosis, autophagy, etc.)
- Intratumor vitamin D metabolism and heterogeneity as well as multidrug resistance mechanisms may hamper the vitamin D effect, but are also potential targets to improve the clinical outcome.

## Acknowledgment

We are very grateful to Dr. Wichor Bramer from the Erasmus MC Medical Library for his excellent support by developing and updating the search strategies.

# Vitamin D status and cancer incidence, mortality, and prognosis

*Hanseul Kim, Irene Shui and Edward Giovannucci*

Harvard TH Chan School of Public Health, Boston, MA, United States

## OBJECTIVES

- Characterize the main types of population-based studies contributing to our knowledge of vitamin D and cancer incidence and progression.
- Summarize the main findings of the cohort studies examining 25-hydroxyvitamin D and cancers of the colorectum, breast, prostate, lung, and other cancers.
- Summarize the main findings of the randomized controlled trials of vitamin D and total cancer incidence.
- Summarize the main findings of the ecologic studies, which determine average vitamin D status in the population, on cancer rates.
- Summarize the findings on vitamin D status and cancer mortality, both in studies among healthy populations and cancer patients (survival).
- Summarize the main findings of the randomized controlled trials of vitamin D and total cancer incidence.
- Summarize the main findings of studies using genetic approaches, including Mendelian randomization, to examine genetic variation of vitamin D status or variation in the vitamin D receptor on cancer incidence and mortality.
- Describe the main challenges inherent in all epidemiologic studies of vitamin D and cancer.

## 1. Introduction

In the 1930s, Peller and Stephenson observed that US Navy personnel had higher rates of skin cancer, but lower rates of other cancers [1]. From this observation, they hypothesized that exposure to sunlight induced skin cancer, which then conferred immunity against other cancers. Several years later, Apperly observed an association between latitude and cancer mortality rate which he attributed to direct effects from exposure to solar radiation [2]. These observations were essentially ignored by the scientific community for about four decades. In the early 1980s, Garland and Garland hypothesized that the potential benefit of sun exposure was attributed to vitamin D, which by then was known to be made from solar ultraviolet B (UV-B) radiation [3]. At the time, there was no mechanism proposed why vitamin D would have anticancer effects. Yet in subsequent years, laboratory studies supported several anticancer properties of vitamin D, including reduced proliferation, invasiveness, angiogenesis, and metastatic potential and increased differentiation and apoptosis [4,5]. These are detailed in other chapters of this section of the book. A growing number of studies have focused on investigating the relationship between vitamin D and cancer prognosis and survival. Indeed, it is plausible that vitamin D could affect tumor biologic aspects of aggressive behavior, such as advanced stage, poor differentiation, metastasis, and survival.

This chapter provides a review and synthesis of epidemiologic evidence focused on the relationship between vitamin D and cancer, and identifies gaps in this evidence where future research is needed. Plausibly, vitamin D could affect either or both cancer incidence (occurrence) or cancer mortality. When considering cancer mortality, it is important to consider that the relevant timing of the exposure on outcome could be during the prediagnostic or postdiagnostic period. In addition, when cancer mortality is an outcome for a cohort that was cancer-free at baseline, cancer mortality may be influenced by either incidence or prognosis. For example, if a risk factor doubled the incidence of a cancer, and the cancers attributed by the risk factor were equally aggressive as those not related to the exposure, we would anticipate a doubling of cancer mortality (assuming no large effect of competing causes). If the action is primarily on survival, the effects can occur either during the prediagnostic period or postdiagnostic period, or both. In this chapter, we first discuss studies that examine vitamin D, and specifically vitamin D deficiency, in relation to incidence, and then on mortality and survival.

## 2. Cancer incidence

Ecologic studies examine rates of cancer incidence or mortality in an entire population, rather than on an individual basis, and then correlate some surrogate of vitamin D to the cancer rates across populations (see Chapter 58). Many of the ecologic studies that initiated the vitamin D–cancer hypothesis were based on cancer mortality in the population. Thus, these studies did not clearly distinguish if any effect, if causal, is primarily due to incidence or mortality. Nonetheless, these studies are compatible with the hypothesis that improved vitamin D status may reduce risk of cancer, and vitamin D deficiency increases risk, “particularly colorectal cancer.” Yet, as many factors other than sun exposure and hence vitamin D status can vary with latitude, which is the typical way vitamin D status is assessed in these studies, there are alternative causal explanations. In the recent two to three decades, there have been a number of reports of prospective cohort studies that have assessed circulating 25-hydroxyvitamin D (25(OH)D) levels in relation to risk of cancer incidence for various cancers using a prospective nested case–control design. In these studies, typically blood samples are taken in a population at baseline and archived, and individuals are followed for cancer risk. The prediagnostic 25(OH)D levels in the subsequent cancer cases and matched controls are assessed and are compared. As these prospective studies, based on a direct measurement of vitamin D status, are generally considered the strongest

design for observational studies of vitamin D (see [Chapter 53](#)), we review primarily these studies here, though other studies, such as those on dietary intake, are also mentioned when relevant.

### 2.1 Colorectal cancer or adenoma

Colorectal cancer was the first malignancy hypothesized to be associated with vitamin D deficiency and has been relatively well studied. Studies that have examined circulating 25(OH)D levels prospectively in relation to risk of colorectal cancer have generally supported an inverse association [6–14]. In an initial metaanalysis of the colorectal cancer studies, based on 535 cases, individuals with  $\geq 82$  nmol/L (33 ng/mL) serum 25(OH)D level had 50% lower incidence of colorectal cancer ( $P < .01$ ) compared with those with vitamin D deficient concentrations at levels of less than or equal to 30 nmol/L (12 ng/mL) [15]. The dose–response appeared to be linear up to a 25(OH)D concentration of at least approximately 90 nmol/L (36 ng/mL), with no obvious threshold or nonlinear relationship. Controlling for multiple covariates, including physical activity, body mass index, and various dietary factors, has had little influence on the findings. These results were confirmed in a metaanalysis of 2630 colorectal cancer cases based on the literature up to December 2009 [16]. In that study, the summary relative risk (RR) was 0.85 (95% confidence interval [CI] = 0.79–0.91) for a 25 nmol/L increment in 25(OH)D. That is, risk decreased by 15% for every 25 nmol/L higher 25(OH)D level.

Many of the existing large cohort studies with plasma or serum biomarkers have published on this association, and most found an inverse association as reflected in the metaanalysis [16]. The large studies that have supported this association have come from diverse populations. These include the Nurses’ Health Study [8], the Health Professionals Follow-Up Study [17], the Women’s Health Initiative [14], the Japan Public Health Center-based Prospective Study [18], the European Prospective Investigation into Cancer and Nutrition study (EPIC), which is a cohort of more than 520,000 participants from 10 western European countries [19], and the Multiethnic Cohort including men and women of Japanese, Latino, African American, White, and Native Hawaiian ancestry [20]. In none of these studies, which had extensive information on various diet and lifestyle factors, was any confounding factor found to completely account for the association. The conclusion was that vitamin D deficiency was associated with increased colon cancer incidence, and there was no evidence of an obvious confounding factor.

Several studies have examined circulating 25(OH)D concentrations and the risk of colorectal adenomas. Adenomas (especially large and high-grade) are well

established precursors to colorectal cancer, and most colorectal cancers are thought to arise from adenomas. Because adenomas are largely asymptomatic, most of the studies compared 25(OH)D levels in adenomas cases to controls who were adenoma-free on colonoscopy or sigmoidoscopy. The studies were based either on initially diagnosed adenomas in the participants, or in adenomas among individuals who had had an adenoma and were then followed for subsequent or recurrent adenomas. In general, these studies suggest either a statistically significant or a nonsignificant inverse association with 25(OH)D and possibly 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) [9–12,21], particularly for advanced adenomas [12]. In a metaanalysis that summarized the results for all available studies of circulating 25(OH)D and adenoma risk [22], higher circulating 25(OH)D was associated with lower risk of colorectal adenomas; the  $\text{RR} = 0.70$  (95%  $\text{CI} = 0.56\text{--}0.87$ ) for high versus low circulating 25(OH)D. The inverse association was stronger for advanced adenoma ( $\text{RR} = 0.64$ ; 95%  $\text{CI} = 0.45\text{--}0.90$ ), though only a fraction of the studies reported on advanced adenomas. In general, the studies of adenomas tend to support an association between vitamin D deficiency and higher risk of colorectal neoplasia.

In another recent metaanalysis, higher circulating 25(OH)D was inversely associated with risk of colorectal adenoma ( $\text{RR}: 0.80$ , 95%  $\text{CI}: 0.71\text{--}0.89$ ). Vitamin D intake was also associated with risk of adenoma ( $\text{RR}: 0.87$ , 95%  $\text{CI}: 0.82\text{--}0.92$  [23]). In addition, colorectal cancer incidence was inversely associated with circulating 25(OH)D ( $\text{RR}: 0.67$ , 95%  $\text{CI}: 0.59\text{--}0.77$ ) and vitamin D intake ( $\text{RR}: 0.85$ , 95%  $\text{CI}: 0.78\text{--}0.93$ ), and higher circulating 25(OH)D was associated with better overall survival ( $\text{RR}: 0.67$ , 95%  $\text{CI}: 0.57\text{--}0.79$ ) and colorectal-specific survival ( $\text{RR}: 0.63$ , 95%  $\text{CI}: 0.53\text{--}0.74$ ). These data suggested that vitamin D may act at various stages of colorectal neoplasia. Notably, the associations tended to be stronger in European and American populations compared with Asian populations, and in populations with higher calcium intake. Asian populations tend to have lower intake of calcium, which could potentially account for the weaker associations with vitamin D.

One study pooled participant-level data of circulating 25(OH)D concentrations from 17 cohorts [24]. This pooled study comprised 5706 colorectal cancer case participants and 7107 control participants. For 30% of participants, 25(OH)D was newly measured, and previously measured 25(OH)D was calibrated to the same assay to permit estimating risk by absolute concentrations. This approach of pooling individual level data gives an advantage over the more typical metaanalyses, which combine data from studies using different assays. In this study, compared with 25(OH)D levels of  $50\text{--}<62.5$  nmol/L, deficient 25(OH)D levels ( $<30$  nmol/L)

were associated with 31% higher colorectal cancer risk ( $\text{RR} = 1.31$ , 95%  $\text{CI} = 1.05\text{--}1.62$ ); 25(OH)D levels of  $75\text{--}<87.5$  nmol/L were associated with 19% lower risk ( $\text{RR} = 0.81$ , 95%  $\text{CI} = 0.67\text{--}0.99$ ); and levels of  $87.5\text{--}<100$  nmol/L were associated with 27% ( $\text{RR} = 0.73$ , 95%  $\text{CI} = 0.59\text{--}0.91$ ) lower risk. The inverse association was stronger in women compared with men.

In various populations, including the United States, colorectal cancer rates have been increasing in those under age 50 in recent decades. It is unknown if vitamin D status is related to this change in rates. One recent study of women in the United States suggested that low vitamin D intake is associated with higher risk of colorectal cancer and adenomas in individuals under the age of 50 [25]. This finding needs replication.

## 2.2 Breast cancer

Breast cancer is one of the cancers that has been hypothesized to be associated with vitamin D. However, the epidemiologic data based on circulating 25(OH)D concentrations have not been consistent, and overall, are not supportive of an association. A metaanalysis in 2011 found different results for circulating 25(OH)D and breast cancer risk based on study design [16]. For prospective studies, where the blood sample was collected prior to the occurrence of breast cancer, no significant association was found. For a 25 nmol/L increment in 25(OH)D, the summary  $\text{RR}$  in the metaanalysis was 0.97 (95%  $\text{CI} = 0.92\text{--}1.03$ ) based on 3145 cases. However, for case–control (retrospective studies), where data were collected after the diagnosis, an inverse association was found (corresponding  $\text{RR} = 0.83$ ; 95%  $\text{CI} = 0.79\text{--}0.87$ ) based on 3030 cases. For the case–control studies, a number of issues were noted, including assessing blood status long after the diagnosis allowing more potential for changes in vitamin D status that do not reflect prediagnostic values, and low participation rates among controls allowing for potential selection bias. Retrospective case–control studies of 25(OH)D and cancer are prone to biases, and the divergent results from prospective and retrospective studies for breast cancer may well reflect these biases.

Similar conclusions were observed in a metaanalysis of prospective studies conducted in 2014 [26]. This metaanalysis included 30 prospective studies and reported a summary  $\text{RR}$  of 0.92 (95%  $\text{CI}: 0.83\text{--}1.0$ ). While not statistically significant, this study was supportive of a modest 8% reduction in risk. No heterogeneity was observed for menopausal status. In another metaanalysis conducted in 2019, an inverse association between 25(OH)D level and breast cancer risk was observed in case–control studies (for high vs. low comparison ( $\text{RR} = 0.57$ , 95%  $\text{CI}, 0.48\text{--}0.66$ ), but not in cohort studies ( $\text{RR} = 1.17$ ,

95% CI, 0.92–1.48) [27]). This metaanalysis also showed no significant association between vitamin D intake and breast cancer risk.

Thus, based on studies of circulating 25(OH)D, no clear association has been observed between 25(OH)D level and breast cancer incidence, at least in studies where the specimen is collected before diagnosis. The main limitation of these studies is that only a single measure of 25(OH)D concentration was made, mostly in middle age, which would tend to attenuate any associations apparent for long-term vitamin D status. The strong inverse association in case–control studies is in stark contrast to the prospective studies. The most likely explanation is reverse causation, that is, breast cancer diagnosis leads to poorer vitamin D status rather than poor vitamin D status leads to breast cancer. For breast cancer incidence, early-life exposure is a particularly important point for etiologic factors, and the studies do not address early-life stage effects.

### 2.3 Prostate cancer

Most of the studies of circulating 25(OH)D level and prostate cancer risk have not found clear risk reductions associated with higher 25(OH)D levels, although some of the studies suggested weak inverse associations [13,28–32]. Two studies [33,34] that tend to support an inverse association between 25(OH)D and prostate cancer risk were conducted in high-latitude Nordic countries, where 25(OH)D levels may be particularly low due to low solar UV-B exposure. However, even the findings from these studies were equivocal. In fact, one of these studies suggested a U-shaped relationship between vitamin D and prostate cancer risk. Large studies also found no association between higher 25(OH)D levels and lower risk for prostate cancer. In the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial, an analysis based on 749 cases and 781 controls found no association, and even a suggestively increased risk of aggressive prostate cancer (Gleason sum  $\geq 7$  or clinical stage III or IV) among men with higher circulating 25(OH)D levels [35]. However, this population by nature of the study design is extensively screened with prostate-specific antigen (PSA) measurements, so the vast majority of the prostate cancers were not of advanced stage (e.g., metastatic), and aggressive prostate cancers were mostly high-grade but organ-confined cancers. In the EPIC study, serum 25(OH)D levels were measured in 652 prostate cancer cases matched to 752 controls from seven European countries [36]. The median follow-up time for the study was 4.1 years. No significant association was found between 25(OH)D concentration and risk of prostate cancer (RR for highest vs. lowest quintile = 1.28, 95% CI = 0.88–1.88; *P* trend = 0.188).

Subgroup analyses showed no significant heterogeneity by cancer stage or grade. In Europe, there is relatively low screening rate for prostate cancer by prostate-specific antigen, so these cases were likely of a relatively more advanced stage than in the studies based in the United States.

The lack of an association between circulating 25(OH)D and risk of prostate cancer was confirmed in a metaanalysis [16]. Based on 3956 cases in 11 identified studies, the summary RR for a 25 nmol/L increment in circulating 25(OH)D was 0.99 (95% CI = 0.95–1.03). Clearly, studies of circulating 25(OH)D concentration have tended not to support an association for prostate cancer, or at best, have yielded equivocal results, with suggestive results possibly at the very deficient low end of the 25(OH)D range (e.g.,  $< 20$  nmol/L). Null associations or even suggestive positive associations for total prostate cancer incidence have been confirmed in more recent metaanalyses [37–39]. The positive association seen in some studies is concerning; however, prostate cancer diagnosis is very prone to detection bias. For example, it is possible that more health-conscious men, who may have higher 25(OH)D levels, may be more likely to have PSA examinations and greater likelihood for detection of otherwise indolent and latent cancers. Populations with very low 25(OH)D concentrations and at notably higher risk of prostate cancer, particularly African Americans, have not received adequate study in regard to vitamin D.

### 2.4 Other cancers

Most cancers besides colorectal, breast, and prostate cancers are generally too uncommon to study with adequate power in individual cohorts. Thus, to address 25(OH)D deficiency in relation to risk of these less common cancers, the Cohort Consortium Vitamin D Pooling Project of Rarer Cancers (VDPP) was formed [40]. This consortium brought together 10 cohorts to conduct a prospective study of the association between concentrations of 25(OH)D and risk of seven less common cancer sites. These cohorts had stored plasma or serum samples and long-term follow-up for cancer. The malignancies studied in the VDPP included endometrial, esophageal, gastric, kidney, non-Hodgkin lymphoma, ovarian, and pancreatic cancers. For this consortium, seven of the cohorts were based in the United States, one in Finland and two in China. The participants were from a wide range of latitudes in various countries, potentially broadening the range of exposure to solar UV-B. The total numbers of cases for each of the cancer sites were as follows: endometrium 830, upper gastrointestinal (esophagus/stomach) 1,065, kidney 775, non-Hodgkin's lymphoma 1353, ovary 516, and pancreas

952. The consortium used a standard laboratory to examine 25(OH)D in a nested case–control sample in the various studies, and then pooled the results. The overall design, description of the cohorts, and statistical methodology were outlined in a methods paper [40]. For all studies, the reported circulating vitamin D categories were <25, 25–<37.5, 37.5–<50, 50–<75, 75–<100, and  $\geq 100$  nmol/L. In general, no overall association was observed in these studies, with no trends approaching statistical significance [40–46]. Some notable subgroup findings are discussed in the following.

For all the cancers, compared with the reference category of 50–75 nmol/L, no comparison group was statistically different, except for an increased risk of pancreatic cancer associated with concentrations of 25(OH)D greater than 100 nmol/L (adjusted odds ratio 2.12, 95% CI = 1.23–3.64). However, a subsequent pooled analysis of other studies in the United States did not confirm this finding and even suggested an inverse association between circulating 25(OH)D and pancreatic cancer risk [47]. For ovarian cancer, as for the other cancers, no overall association was observed, although there was statistically significant interaction with body mass index (BMI) ( $P < .01$ ), with an inverse association suggested only for women with a body mass index  $\geq 25$  kg/m<sup>2</sup> ( $P$  trend = 0.01). Two prospective nested case–control studies conducted in the Finnish Maternity Cohort provide evidence of an inverse association between 25(OH)D and ovarian cancer for a relatively young age-at-onset group of ovarian cancer. In the first report, the RR among women with insufficient (<75 nmol/L) serum 25(OH)D concentration was 2.7 (95% CI = 1.0–7.9) compared with that among those with sufficient (>75 nmol/L) serum 25(OH)D concentration [48]. In the second report, having sufficient compared with insufficient serum 25(OH)D levels was associated with a significantly decreased risk of ovarian cancer (RR 0.32; 95% CI = 0.12–0.91) [48].

In the VDPP, overall, no association was observed between 25(OH)D level and risk of upper gastrointestinal cancer [42]. However, some difference appeared by race. Among Caucasians, no overall trend was observed, but above levels of 25 nmol/L of 25(OH)D, a suggestive inverse trend was observed with increasing levels, though those with levels <25 nmol/L were not at higher risk. In contrast, among Asians, a significant positive trend was noted with higher circulating 25(OH)D ( $P$  trend = 0.003). However, in one of the two main Asian cohorts (Shanghai Men's Health Study), the median follow-up time was only 1.7 years, suggesting the possibility of reverse causation. Further suggestive of reverse causation, the association with 25(OH)D was stronger in follow-up less than 2 years than in follow-up time  $\geq 2$  years. This may suggest that latent cancers affected 25(OH)D levels.

## 2.5 Randomized controlled trial studies of vitamin D and total cancer incidence

In recent years, data on vitamin D supplementation and cancer incidence from randomized controlled trials (RCTs) have increased. In most studies, RCTs generally have not been conducted for cancer incidence as a primary outcome. The largest RCT, which did have cancer incidence as a primary endpoint, was the Vitamin D and Omega-3 Trial (VITAL). This was a large-scale randomized trial conducted in the United States in which over 20,000 participants were randomized to take either 2000 IU of vitamin D<sub>3</sub> (cholecalciferol) per day or a placebo over a 5-year period. The primary endpoints were total cancer and major cardiovascular events; site-specific cancers and cancer mortality were secondary endpoints. No association was observed for vitamin D versus placebo with cancer incidence. The hazards ratio (HR) was 0.96 (95% CI = 0.88–1.06) [49]. Another recent study was the D-Health Trial [50], a randomized placebo-controlled trial in Australia, with intervention for 5 years, and with 5 years of additional passive follow-up. 21,315 participants aged 65–84 years were recruited and given monthly oral dose of 60,000 IU of cholecalciferol or placebo. This study also showed no effect on cancer incidence; the hazard ratio was 1.01 (95% CI = 0.81–1.25).

The available studies have generally been underpowered to examine specific cancer subtypes, but had reasonable power to examine total cancer incidence. A recent metaanalysis considered the available RCTs of vitamin D supplementation and total cancer incidence for studies up to January 2022 [51]. For total cancer incidence (12 trials), the summary RR for vitamin D supplementation versus control group was 0.99 (95% CI, 0.94–1.03;  $P = .54$ ;  $I^2 = 0\%$ ). No significant association was indicated for any of the daily versus infrequent large-bolus dosing strategies ( $P_{\text{heterogeneity}} = 0.40$ ). The finding was statistically robust, as illustrated by the tight confidence intervals. A wide range of starting 25(OH)D levels were seen, with the mean/median levels of circulating 25(OH)D in the participants ranging from approximately 38–83 nmol/L at baseline. By dosing frequency, eight RCTs provided vitamin D<sub>3</sub> supplements daily (400–4000 IU/day), while five RCTs provided a large bolus dose infrequently (20,000 IU/week to 500,000 IU/year). The levels in the intervention groups elevated to 54–136 nmol/L at a point during the follow-up. The mean durations of the total follow-up periods, including intervention and postintervention follow-up, ranged approximately 3–10 years. An unexpected but potentially interesting result was when metaanalyses were conducted for each category of BMI, the results were significantly heterogenous across

BMI level ( $P_{\text{heterogeneity}} = 0.02$ ), and a significant inverse association observed only among normal weight individuals (RR, 0.76; 95% CI, 0.64–0.90;  $P = .001$ ), but not among overweight or obese individuals. Yet this result was largely driven by the VITAL study and thus requires confirmation.

Although considered the gold standard for evidence, randomized controlled trials (RCTs) generally have limitations for studying a complex association such as that for vitamin D and cancer risk. Adult cancers typically arise through a long multistage process. At what stage the exposure (i.e., vitamin D) is relevant and the required duration are not accounted for in studies that implicitly study relatively short durations of vitamin D status at late stages of the cancer occurrence. Furthermore, it is important to choose an appropriate dose, and to select a study population that is able to benefit from supplementation (e.g., one that is deficient in vitamin D). Even if the study design is appropriate, there may be practical issues such as ensuring compliance and avoiding contamination (e.g., those assigned to the placebo begin taking vitamin D supplements) that can undermine the study. If the conditions for the study design, power, and execution are not met, a real association could be attenuated and even missed. Thus, while RCTs could provide the strongest evidence for a causal association, RCTs with null results should be considered in the context of other lines of evidence and may not necessarily be the final word. It is also relevant that the metaanalysis was able to only consider total cancer incidence. Whether there is benefit for specific types of cancer remains an open question.

### 3. Cancer mortality and survival

The number of individuals with cancer worldwide is very large and increasing. For example, currently, in the United States (US) alone, there are more the 15 million cancer survivors, a number that is projected to grow to more than 20 million by 2026 [52]. Additionally, there is a high prevalence of vitamin D deficiency among those diagnosed with cancer; one review of 37 studies found that up to 67% of patients with cancer had vitamin D deficiency (levels less than 20 ng/mL or 50 nmol/L) [53]. Thus, if there is a causal relationship between vitamin D status and reduced cancer survival and prognosis, intervening on the population at large or among cancer survivors could have a large public health impact. In addition, although vitamin D does not appear to have a very strong association with total cancer incidence, other than perhaps colorectal cancer, it is plausible that it may affect cancer mortality by reducing the aggressiveness (e.g., metastatic potential) of cancers that occur.

### 3.1 Sun exposure

Latitude or region UV-B radiation has been examined in relation to cancer mortality in several ecologic studies. In general, ecologic studies have found that lower mortality rates of numerous types of cancer are correlated with regions with greater solar UV-B exposure [54–63]. The geographical association between UV-B exposure and cancer was stronger for cancer mortality as the endpoint than for incidence for many cancers in the United States and China [59,60]. An important limitation of these ecologic studies is that potential confounding factors related to regional differences in solar UV-B radiation could account for the associations. However, suggestive evidence that an inverse association between regional solar UV-B exposure and cancer mortality may be causal is that this association is observed in regions outside of the United States, including in Japan (for digestive organ cancers) [58], Spain [62], and China [59]. Thus, a putative confounding factor would have to have similar relationships with regional solar UV-B exposure in these diverse populations. A strength of ecologic studies is that they may provide some indication of long-term sun exposure, including during childhood and adolescence, thus preceding the onset of cancer by many years. Ecologic studies are discussed in more detail in [Chapter 53](#).

Unlike ecologic data, case–control and cohort studies assess exposure and outcome at the individual level. Confounding may be better controlled because typically more detailed information can be assessed on other covariates. Several case–control and cohort studies have assessed sun exposure in relation to cancer mortality. Freedman et al. [64] conducted a large US death certificate–based case–control study of cancer mortality to examine associations with residential and occupational exposure to sunlight. Residential sun exposure was inversely associated with mortality from breast, ovarian, prostate, and colon cancers. Mortality from nonmelanoma skin cancer, acting as a “positive control,” was positively associated with residential sun exposure. An analysis of NHANES I data based on 59 fatal prostate cancer cases among 3426 non-Hispanic white men found that frequent recreational sun exposure in adulthood was associated with a lower risk of fatal prostate cancer (RR = 0.47), and men who were both born in and had the longest residence in a high solar radiation region also had a lower risk of fatal prostate cancer (RR = 0.34) [65]. Conversely, a large prospective US study of almost 350,000 non-Hispanic white participants found that higher exposure to UV-B at baseline residence was associated with a small increased risk when comparing quartile 4 to quartile 1 (RR = 1.04, 95% CI = 1.02, 1.05) of overall cancer mortality in men. The main driver of this association was deaths from lung

cancer. While this study had large numbers and the ability to control for several confounding factors, UV-B exposure was only considered at baseline when participants were between 50 and 71 years of age and therefore may not reflect earlier-life exposures due to population mobility [66].

Region of residence as a surrogate of solar UV-B radiation and vitamin D status may be affected by increasing urbanization, more time spent indoors, winter vacations to sunny climates, and sun avoidance or sunscreen use. These factors could vary among populations and change over time. Some studies have used factors such as history of sunburns or holidays in a hot climate as proxies for sun exposure, and the findings have been mixed. A Swedish prospective cohort study of almost 40,000 women aged 30–49 years followed for a mean of 14.9 years found a protective association with all-cause mortality, but did not find an association between history of sunburns or going on sunbathing vacations between age 10 and 39 years and cancer-specific mortality. Artificial UV exposure was associated with increased all-cause and cancer-specific mortality [67]. An Italian study of over 2000 melanoma patients found that holidays with sun exposure were associated with favorable prognostic factors [68]. An international population-based study among 3578 cases of melanoma with a mean 7.4 years of follow-up found that having at least one sunburn within 10 year of diagnosis was associated with increased survival, but other measures of sun exposure, including water activities, skin damage, sunny holidays, and estimated ambient UV-B dose based on residence, were not associated with survival [69].

Season of diagnosis has also been used as a proxy for vitamin D status. Because season of diagnosis represents only a small fraction of the time of cancer development, for it to be relevant would require some acute benefit, such as an interaction with treatment shortly following diagnosis. Some studies found that patients diagnosed with cancer and/or treated during the summer and autumn months, when vitamin D status is higher, have a better prognosis than those diagnosed and/or treated during the winter months [70–76], while others did not [77,78]. While season of diagnosis may be correlated with circulating vitamin D levels, other factors could also confound the association. For example, a study based in Sweden did not find this pattern, but an explanation could be that the structure of the healthcare system and vacationing patterns might lead to disease diagnosed at a later stage in the summer [78].

### 3.2 Circulating 25(OH)D

The circulating 25(OH)D concentration is generally considered the best measure for total vitamin D status.

Serum 25(OH)D has a relatively long half-life of about 2–3 weeks and can provide a reasonable indicator of long-term (5–15 years) vitamin D status (see [Chapter 53](#)). The majority of studies to date that have assessed circulating 25(OH)D and cancer survival have used measures of postdiagnostic 25(OH)D. The time of blood collection varies in these studies from very close to diagnosis and prior to treatment to over a longer period after diagnosis. Only a few studies have collected prediagnostic blood samples, and the availability of multiple longitudinal samples is generally not feasible for large cohort studies. In studies in which 25(OH)D is measured after diagnosis in cancer patients, potential reverse causation needs to be considered, due to potential behavior/lifestyle changes following diagnosis or the disease itself affecting 25(OH)D levels. There is some evidence that the prevalence of 25(OH)D insufficiency is higher in cancer patients compared with the general population [79]. In particular, for blood collected at longer periods postdiagnosis, patients with more advanced disease with a worse prognosis may have lower vitamin D levels (for example, due to less sun exposure or physical activity). Studies in which the results were stronger when limiting the analyses to early stage cases or in studies that only examined early stage cases may be less susceptible to this possibility. It is also possible that if blood samples are collected posttreatment, that treatment could modify 25(OH)D levels. In studies that assess 25(OH)D in the prediagnostic period, reverse causation is less likely, but without multiple blood measurements, we cannot definitively determine the most relevant timing of the association, as prediagnostic and postdiagnostic 25(OH)D levels are likely to be correlated. Results of studies of circulating 25(OH)D concentration and cancer mortality, focusing on colorectal, breast, prostate, lung, and melanoma cancers, are briefly reviewed here.

### 3.3 Colorectal cancer

There is relatively consistent evidence for a protective association of circulating 25(OH)D concentrations and cancer prognosis with colorectal cancer. Several metaanalyses and reviews have found consistent evidence supporting a benefit of higher circulating 25(OH)D and survival and prognosis [79–83]. Some studies measured 25(OH)D from blood collected postdiagnosis [81,84,85], and others collected blood prediagnosis [86–88]. Zgaga et al. [81], in a prospective study of 1598 stage 1 to III colorectal cancer patients who experienced 363 CRC-specific deaths over a median of 9 years of follow-up, found that circulating 25(OH)D sampled postoperatively was inversely associated with colorectal cancer-specific mortality; the HR for the highest versus

lowest tertile = 0.68 (95% CI: 0.50–0.90) after multivariable adjustment. When they combined their results in a metaanalysis of four other published studies, they found the adjusted HR was 0.67 (95% CI, 0.54–0.81). Some studies have found that results varied by stage; one study found stronger association in stage II cancers [81], while another found stronger results in more advanced stage colorectal cancers [88]. Two studies specifically assessed advanced-stage disease and one found a protective association [89], while the other found no association [90].

A metaanalysis that examined circulating 25(OH)D in relation to colorectal cancer outcomes was conducted in 2018 [83]. This analysis included 11 original studies with a total of 7718 colorectal cancer patients. When comparing highest versus lowest categories of 25(OH)D, the pooled HR and 95% CI were 0.68 (0.55–0.85) and 0.67 (0.57–0.78) for overall and colorectal cancer-specific survival, respectively. A dose–response relation was observed. This recent metaanalysis provided strong evidence of an association between higher blood 25(OH)D concentrations and better overall and cancer-specific survival in colorectal cancer patients.

### 3.4 Breast cancer

Similar to colorectal cancer, several recent reviews and metaanalyses have found evidence favoring a protective association of higher circulating 25(OH)D with breast cancer prognosis and survival [79,80,82,91–93]. A metaanalysis in 2014 [92] included eight independent studies and reported low circulating 25(OH)D was associated with increased overall mortality ( $RR_{\text{lowest vs highest quartile}} = 1.52$ ; 95% CI: 1.22–1.88) and increased breast cancer-specific mortality ( $RR = 1.74$ ; 95% CI: 1.23, 2.40). These results have been largely confirmed in more recent metaanalyses [94,95].

Most studies have been conducted in early-stage (stage I–IIIa) patients. One study that examined both early- and late-stage patients found that the association was limited to those diagnosed in the early stage [92], which could be due to more advanced cancers being less amenable to lifestyle factors. The protective association may be stronger in studies with blood collected closer in time to diagnosis as two studies with longer times from diagnosis to blood collection did not show an association [91]. One potential explanation could be that circulating 25(OH)D levels may change due to therapy or changes in lifestyle in response to the cancer diagnosis or worsening disease [96]. For example, one study found that the association of circulating 25(OH)D and mortality in breast cancer patients was only statistically significant in those who did not receive chemotherapy or whose blood was collected prior to

chemotherapy [97]. However, three other studies in women with early-stage breast cancer participating in different breast cancer treatment trials have not observed associations between circulating 25(OH)D level and breast cancer prognosis [98–100].

Explanations for the differences between the results of the nontherapeutic observational studies and the results of these trials could be due the more restrictive study entry criteria for the trials resulting in a more homogenous population, or the potential for the adjuvant treatments to negate the adverse impact of low circulating 25(OH)D. Additionally, no information was available on vitamin D supplementation after blood draw, and studies have shown this to be common in recently diagnosed breast cancer patients [101].

### 3.5 Prostate cancer

The literature on prostate cancer mortality and prognosis with respect to circulating 25(OH)D is relatively supportive of an inverse association but overall inconsistent. Three studies have assessed postdiagnostic circulating 25(OH)D level and prostate cancer mortality, with one finding a protective association [102], and two others finding no significant association [103,104]. One of the studies that did not find an association enrolled only men with stage IV disease and had a relatively short median follow-up of 31 months [104]. As discussed previously, it is possible that more advanced cancers may be less susceptible to the influence of vitamin D levels and modifiable factors in general. Studies assessing prediagnostic circulating 25(OH)D level and prostate cancer mortality are also mixed. A cohort study of Finnish male smokers did not find an association of 25(OH)D level with incident fatal prostate cancer [105]. A US-based cohort study of males found that those in the highest quartile of plasma 25(OH)D had a 57% reduction in the risk of lethal prostate cancer compared with those in the lowest quartile [106]; data from this study were combined with another male US cohort study and men in the lowest quartile of prediagnostic plasma 25(OH)D had a 60% higher risk of progression to prostate cancer death compared with those in the highest quartile [107]. However, a pooled analysis combining the three cohorts mentioned above and two additional cohorts with a total of 518 fatal prostate cancer cases and 2986 controls did not find a significant association [108].

Two published survival analyses found evidence for a protective association. A Swedish study with 943 cases of prostate cancer and 169 deaths due to prostate cancer over a median of 9.1 years found an approximately 50% lower risk of prostate cancer-specific mortality in those with vitamin D levels above

85 nmol/L compared with those with 68 nmol/L or lower [109]. Interestingly, the cohort study of Finnish male smokers, who did not find an association of 25(OH)D with incidence of fatal prostate cancer compared with controls, did observe a statistically significant ~30% reduction of progression to prostate cancer–specific death among men diagnosed with prostate cancer who had the highest quintile of pre-diagnostic serum 25(OH)D compared with the lowest quintile [110]. The authors posited that the more recent survival analysis had longer follow-up and more end-points and thus may have been more sufficiently powered to detect an association. Another difference was that the prior analysis assessed the endpoint of fatal prostate cancer incidence compared with controls, whereas the later analysis assessed survival after diagnosis among cases only.

A dose–response metaanalysis examining circulating 25(OH)D level and mortality in prostate cancer patients was conducted for studies up to 2018 [111]. This metaanalysis, which included seven eligible cohort studies with 7808 cancer participants, supported a beneficial association. Specifically, the summary HR of prostate cancer–specific mortality for an increment of 20 nmol/L in circulating vitamin D level was 0.91, with 95% CI: 0.87–0.97, and the corresponding HR for all-cause mortality was 0.91 (95% CI: 0.84–0.98).

### 3.6 Lung cancer

The evidence for lung cancer survival is mixed. Most studies have measured postdiagnostic circulating 25(OH)D. A Norwegian study of 210 lung cancer cases [84] and a US study of 447 early-stage non–small-cell lung cancer cases [112] observed better survival with higher circulating 25(OH)D measured shortly after diagnosis. However, a small Chinese study of 87 cases of non–small-cell lung cancer did not observe a protective association [113]. Two studies have focused on advanced non–small-cell lung cancer with 294 cases [114] and 359 cases [115]; both did not report a difference in survival by circulating 25(OH)D levels. A recent study measured prediagnostic circulating 25(OH)D in 500 Finnish male smokers with lung cancer and did not find a significant association with survival. This study found suggestive protective effects for the histological subtypes adenocarcinoma and small cell carcinomas, but the estimates were based on a relatively small number of cases and were not statistically significant [116]. Another study found that having a higher prediagnostic blood level of 25(OH)D was associated with decreased lung cancer mortality in nonsmokers only [117].

### 3.7 Other cancers

A metaanalysis of studies conducted through December 2013 found that in addition to the protective association for breast and colorectal cancer described before, higher 25(OH)D levels were also associated with better lymphoma outcomes [80]. In addition, three studies have also found that higher 25(OH)D level collected at or near diagnosis was associated with better prognosis in melanoma patients [118–120]. A study of circulating 25(OH)D levels prior to chemotherapy initiation in advanced pancreatic cancer patients ( $n = 256$ ) observed no relationship between 25(OH)D levels and progression free or overall survival [121]. The advanced stage of disease (median survival was <6 months) and the fact that the majority of patients had deficient (44.5%) or insufficient (22.5%) levels of vitamin D (<20 and <30 ng/mL, respectively) may have limited the ability to observe an association. Finally, a metaanalysis of 17 cohort studies found a statistically significant inverse association between baseline 25(OH)D levels and cancer death; RR of total cancer mortality for the bottom compared with the top two-thirds of baseline 25(OH)D concentration was 1.25 (95% CI: 1.10–1.43) [122].

### 3.8 Studies using predicted 25(OH)D

Another approach to estimate circulating 25(OH)D levels when blood samples are unavailable has been to use a predicted surrogate of 25(OH)D. The predicted 25(OH)D approach may have some advantages and disadvantages compared with the use of a single measurement of circulating 25(OH)D in epidemiologic studies [123]. For example, it may be more logistically feasible to gather information on predictors of vitamin D (diet, sun exposure, physical activity, skin characteristics) on larger numbers of people, than to prospectively collect blood samples. However, there is substantial unexplained variability of 25(OH)D levels in these models, and they should not be used to measure absolute levels of 25(OH)D exposure. Instead, the predictive 25(OH)D levels are useful markers of relative rather than absolute vitamin D status. One analysis in the Health Professionals Follow-Up Study used a predicted surrogate of 25(OH)D to examine risk of total cancer mortality [124]. The analysis was based on a two-stage approach. In the first stage, circulating 25(OH)D was measured in a sample of 1095 men in this cohort. Then, geographical region, skin pigmentation, dietary and supplement intake, BMI, and physical activity (a surrogate of potential exposure to sunlight UV-B) were used to develop a predicted 25(OH)D score using multiple linear regression. In the second stage, the score was calculated for each of approximately 47,000 men, and then this

variable was examined in relation to subsequent risk of cancer mortality. A 25 nmol/L increment in predicted 25(OH)D was associated with a 29% reduction in total cancer mortality. The associations persisted even when adjusted for potential confounders such as smoking, and including body mass index and physical activity, which contribute to the predicted 25(OH)D. Associations were particularly strong for digestive cancers (colorectal, pancreatic, stomach, and esophageal cancers), oral/pharyngeal cancers, and leukemias.

Predicted 25(OH)D level at diagnosis was examined in relation to mortality among 1017 participants in the Nurses' Health Study and the Health Professionals Follow-Up Study who were diagnosed with colorectal cancer [125]. Those in the highest quintile compared with the lowest quintile of predicted 25(OH)D levels had a 50% decreased risk of cancer-specific mortality and a 38% decreased risk of overall mortality. These associations persisted even after adjusting for prediagnostic predicted 25(OH)D levels, suggesting that intervening on vitamin D status at cancer diagnosis could be relevant timing for improving prognosis.

### 3.9 Studies of vitamin D intake

Vitamin D intakes are relatively low in general, and in most populations, more vitamin D is made from sun exposure than is ingested from food sources. Nonetheless, vitamin D intake is an important contributor to 25(OH)D levels, especially in winter months in regions at high latitudes when it may be the predominant or sole contributor. Although a large proportion of cancer patients report using vitamin and mineral supplements, including those containing vitamin D, the literature assessing associations with cancer prognosis and mortality is still quite limited [50].

The After Breast Cancer Pooling project, a consortium of four cohorts of 12,019 breast cancer survivors from the United States and China, assessed postdiagnosis, post-treatment vitamin D supplement use, and breast cancer outcomes. No association was observed between vitamin D supplement use and overall breast cancer recurrence or mortality. However, when stratified by estrogen receptor (ER) status, vitamin D supplementation was associated with a significant 46% decreased risk of recurrence among ER positive, but not of ER negative tumors ( $p$ -interaction = 0.01) [126]. Dose and duration of vitamin D supplementation use was not assessed in this study. A study of women aged 55 years and older in the United Kingdom Clinical Practice Research Data-link found that women with breast, colorectal, lung, ovarian, or uterine cancer who had exposure to three or more prescriptions in the 5 years prior to cancer diagnosis for vitamin D supplements did not have better

survival compared with women who received one to two prescriptions [127]. Exposure misclassification of women's vitamin D status may be a major limitation to this study as there was no information on vitamin D supplements that were not prescription-based or other sources of vitamin D, actual adherence to the prescribed vitamin D, or vitamin D intake postdiagnosis. Additionally, the follow-up for mortality in this study was relatively short (median 30.4 months). Finally, a large US study of 2284 colorectal cancer patients (408 colorectal cancer-specific) observed no association between pre-diagnostic vitamin D intake and colorectal cancer-specific survival [128].

### 3.10 Randomized controlled trials

Randomized controlled interventions (RCTs) are considered the "gold standard" for establishing a causal association because ideally, through effective randomization, confounding can be largely eliminated as an alternative explanation for the observed results. Several trials have investigated various doses of supplemental vitamin D and overall cancer mortality as a secondary endpoint. Relatively few RCTs, for example, VITAL, had total cancer mortality as a prespecified secondary endpoint. Main limitations of the RCTs to date are that most have been conducted in older populations for non-cancer primary endpoints, and the sample sizes and study duration have been limited to assess cancer survival endpoints. The doses have varied, with some arguably too low. The mode of intervention included daily doses and less frequent high-dose bolus dosing. Some of the major RCTs are described briefly here:

- The Women's Health initiative (WHI) study was a randomized placebo-controlled trial of 400 IU vitamin D plus 1000 mg of calcium per day in 36,282 postmenopausal women. A post hoc analysis of the WHI study for cancer mortality showed that, although not statistically significant, women randomized to vitamin D and calcium had a reduced risk of cancer mortality (344 cancer deaths in the treatment group vs. 382 in the placebo group;  $RR = 0.89$ ; 95%  $CI = 0.77-1.03$ ) [129]. In a reanalysis of the WHI study limited-access dataset in 15,646 women (43%) who were not taking personal calcium or vitamin D supplements at randomization, the vitamin D and calcium intervention significantly decreased the risk of total, breast, and invasive breast cancers by 14%–20% and nonsignificantly reduced the risk of colorectal cancer by 17%, but no association was seen in women taking personal calcium or vitamin D supplements [130].
- In an RCT conducted in the United Kingdom, 2686 subjects aged 65–85 years old were randomized to

- receive either 100,000 IU of vitamin D<sub>3</sub> every 4 months (equivalent to 820 IU daily) or a placebo over a period of 5 years [131]. After treatment, the 25(OH)D level was 74.3 nmol/L in the vitamin D–treated group and 53.4 nmol/L in the placebo group (a ~21 nmol/L difference due to supplementation). There was a nonsignificant reduced risk of cancer mortality (63 cancer deaths in the treatment group vs. 72 in the placebo group; RR = 0.86; 95% CI = 0.61–1.20).
- Another UK study included 5282 subjects (85% women) aged 70 years and older who were randomized to daily 800 IU vitamin D<sub>3</sub>, 1000 mg calcium, both or placebo for 24–62 months with a 3-year follow-up period after the intervention. This study found a protective, but nonsignificant reduced risk of cancer mortality between those allocated vitamin D compared with those who did not receive vitamin D (HR = 0.85; 95% CI = 0.68–1.06) [132].
  - A large-scale randomized trial was conducted in the United States (Vitamin D and Omega-3 Trial) in which 20,000 participants have been randomized to take either 2000 IU of vitamin D<sub>3</sub> per day or a placebo over a 5-year period [133,134]. The primary endpoints were total cancer and major cardiovascular events; site-specific cancers and cancer mortality were secondary endpoints. While no effect was seen for cancer incidence, the hazard ratio was suggestive (HR = 0.83 (95% CI = 0.67–1.02) for cancer death [49]. The result was statistically significant when the first 2 years of follow-up (a prespecified secondary endpoint) was conducted. In addition, in a secondary analysis of this trial, the authors found a significant reduction in advanced cancers (metastatic or fatal) for those randomized to vitamin D supplementation compared with placebo (HR = 0.83; 95% CI = 0.69–0.99) [135].
  - Vitamin D and Longevity trial in the United Kingdom—is a feasibility trial of 1600 men and women randomized to 100,000 IU monthly (3300 IU/day) of oral vitamin D<sub>3</sub> or placebo—if successful, they will continue on to recruit 20,000 subjects (<http://vidal.lshtm.ac.uk/>).
  - The Finnish Vitamin D trial originally aimed to randomize 18,000 Finnish participants aged 60 (men) or 65 (women) and older to either 1600 IU/day or 3200 IU/day of vitamin D<sub>3</sub>, or placebo, but has since reduced the overall sample size to 2500 because of difficulties in recruitment and funding (CTG: NCT01463813). In this trial, vitamin D<sub>3</sub> supplementation did not lower the incidences of invasive cancer among older adults, possibly because most participants had sufficient vitamin D at baseline [136].
  - D-Health Trial [137] in Australia is a randomized placebo-controlled trial, with intervention for 5 years, and with 5 years of additional passive follow-up.

21,315 participants aged 65–84 were recruited and given monthly oral dose of 60,000 IU of cholecalciferol or placebo with the primary outcome being all-cause mortality and secondary outcomes being mortality from other causes including cancer. Vitamin D administration did not reduce cancer mortality in this trial (Hazard ratio = 1.15; 95% CI = 0.96–1.39) [138].

While overall the RCTs individually did not find significant results for vitamin D supplementation, a number of the studies found suggestive though not significant 10%–15% reductions in risk. Individually, the studies were not powered to show that such associations would be statistically significant. A recent meta-analysis considered the available RCTs of vitamin D supplementation and total cancer mortality for studies up to January 2022 [51]. Based on a total of six trials assessing total cancer mortality, the summary RR for vitamin D supplementation versus control group and total cancer mortality was 0.92 (95% CI, 0.82–1.03; *P* = .17). Interestingly, a significant inverse association emerged among studies that tested daily vitamin D supplementation (RR, 0.87; 95% CI, 0.78–0.96), but not among studies that tested infrequent large-bolus supplementation (RR, 1.05; 95% CI, 0.88–1.26). Of note, in the VITAL trial, a significant inverse association was observed only among normal weight individuals (RR, 0.58; 95% CI, 0.39–0.86), but not among overweight or obese individuals. No other study reported on the stratification by body mass index.

The results of these trials have the potential to provide more evidence for a causal association; however, they also are subject to the practical limitations discussed previously, including limited follow-up, late etiologic exposure period, the selection of an effective dose, and that they were designed for primary endpoints other than cancer mortality. There were also issues such as potential problems with compliance and use of vitamin D supplements other than those assigned in the study. All of these factors could obscure a true association, if one exists. Nonetheless, there is suggestive evidence from the RCTs of a late effect of vitamin D status on cancer mortality, which is supported by the observational data summarized in this chapter.

The role of vitamin D supplementation as an adjuvant to traditional cancer therapy is of interest. Zeichner et al. [139] conducted a retrospective observational study of 308 patients from a cancer center in Miami who received chemotherapy for nonmetastatic HER2+ breast cancer patients. They found that those patients who took vitamin D supplements had significantly improved disease-free survival compared with those on chemotherapy who did not take a vitamin D supplement.

The mean dose of vitamin D was 10,472 IU/week (1500 IU/day). These promising findings combined with the favorable risk–benefit ratio of vitamin D supplementation may warrant the design of RCTs among cancer patients. As vitamin D insufficiency and deficiency is prevalent among those diagnosed with cancer, RCTs could be designed in which high doses of vitamin D are provided to the randomized subjects to rapidly increase vitamin D stores at the time shortly before treatment to test the hypothesis that vitamin D status may favorably interact with treatment or promote better prognosis independent of treatment. Indeed, randomized trials of vitamin D supplementation as adjuvant therapy for melanoma [140,141] are in progress. However, it is important to note that the feasibility of these trials may be limited in some populations because many cancer patients are already taking or prescribed supplements [50,101].

#### 4. Genetic variation and gene expression in the vitamin D pathway

##### 4.1 Common variation

Several single-nucleotide polymorphisms (SNPs) associated with serum 25(OH)D levels have been identified, including variants in *GC* (or *DBP*), *CYP2R1*, and *DHCR7* [142] (see Chapter 60). If the association between higher 25(OH)D level and lower cancer mortality were causal, one would then expect to see a relationship between the SNPs that predict levels of 25(OH)D and cancer. Based on the concept of “Mendelian randomization,” a person’s genetic variation should not be confounded by other cancer risk factors—see Chapter 61. Limitations to these studies are that the SNPs identified only explain a small amount of variation (<5%) of 25(OH)D concentration, so most studies would not be powered to detect the corresponding small association with disease risk. Additionally, the relationship of the SNPs and 25(OH)D levels is complicated. For example, the SNPs most strongly associated with 25(OH)D levels were in the *DBP* (*GC* or *DBP*) and are also related to levels of this binding protein [143]. If these SNPs also affect the *DBP*’s affinity, genetically determined circulating 25(OH)D levels may not reflect true bioavailability. Thus, a null finding in these studies would not exclude a causal relationship between vitamin D and cancer.

In addition to Mendelian randomization studies, other studies have more generally assessed whether polymorphisms in genes involved in the vitamin D signaling pathway or its metabolism are associated with cancer prognosis or mortality. If relevant genetic polymorphisms are consistently associated with a

cancer, they lend additional support that vitamin D is the causal factor rather than confounding by another associated risk factor. In this section, we summarize studies that have assessed vitamin D–related genetic variation with mortality or survival in overall cancer, as well as for specific cancers, including colorectal, breast, prostate, lung, and melanoma. The subject of polymorphisms is further discussed in Chapters 60 and 61.

A study combining three Danish cohorts with almost 100,000 participants and 10,349 deaths (2839 from cancer) created an allele score from genetic variants in *DHCR7* and *CYP2R1* and found that each increase in allele score was associated with a 1.9 nmol/L lower 25(OH)D concentration [144]. As expected, the *DHCR7* and *CYP2R1* allele score was not associated with other lifestyle factors and thus is unlikely to be confounded. They did not examine SNPs in the *DBP* because of concern that the genetically determined 25(OH)D may not reflect bioavailable 25(OH)D. The odds ratio for a genetically determined 20 nmol/L lower plasma 25(OH)D concentration was 1.30 (95% CI = 1.05–1.61) for all-cause mortality and 1.43 (95% CI = 1.02–1.99) for total cancer mortality. The authors concluded that their results are compatible with the hypothesis that genetically low 25(OH)D concentrations may be causally associated with cancer-related mortality. However, other large studies did not find an association between genetically determined variation in 25(OH)D and cancer mortality [145].

Traditionally, Mendelian randomization studies assume a linear dose–response relation, that is, that the effect of an increase in 25(OH)D is constant across the range of 25(OH)D in the studied population. For example, a population increase for a level of 20–30 nmol/L has an equivalent benefit as an increase from 80 to 90 nmol/L. This assumption may not be realistic and would cause a loss of power if the association is nonlinear. One study examined nonlinear dose–response relationships of 25(OH)D concentrations with various mortality endpoints, including cancer mortality [146]. This study suggested that inverse associations between genetically predicted 25(OH)D concentrations and mortality outcomes were limited to the stratum of the population with low “nongenetic” related 25(OH)D concentrations (calculated as the residual from regression of 25(OH)D on the mean-centered genetic risk score). For total cancer mortality ( $n = 12,804$  events), there was no overall association of genetic 25(OH)D—a 10 nmol/L increment in genetic 25(OH)D had an odds ratio of 0.98 (95% CI = 0.93–1.02;  $P = .29$ ). However, the same OR for those with 25(OH)D levels <25 nmol/L was 0.81 (0.65–1.02;  $P = .09$ ), and for those with levels 25–49 nmol/L, it was 0.93 (0.87–1.00;  $P = .046$ ). This

finding suggests that circulating 25(OH)D is associated with decreasing risk of cancer mortality up to around 50 nmol/L with no further benefit thereafter, though the statistical methods are novel and need confirmation.

*Vitamin D receptor (VDR)* polymorphisms have traditionally been one of the most studied candidate genes related to the vitamin D pathway, though their functionality is not fully understood. *VDR* polymorphisms were not associated with colorectal cancer—specific or overall survival in two European studies; one study had 1202 colorectal cancer cases and 444 colorectal cancer—specific deaths [147], and the other combined two cancer cohorts for a total of 1397 cases and 336 CRC-specific deaths [148]. However, both of these studies only assessed a few of the most common *VDR* polymorphisms.

An analysis in a US cohort of men assessed 97 SNPs from seven vitamin D—related genes (*CYP27B1*, *CYP27A1*, *GC*, *VDR*, *RXR $\alpha$* , *CYP2R1*, *CYP24A1*) among 114 men with lethal prostate cancer and 1244 controls. The authors used a pathway-based approach to assess whether multimarker SNP-sets in the seven genes were associated with lethal prostate cancer and found that the seven gene SNP-set and the individual gene SNP-sets defined by the *VDR* and *CYP27A1* genes were associated with risk of lethal prostate cancer [106]. Measuring the joint effect of multiple SNPs could potentially capture more of the true association when compared with individual SNP analyses. However, a larger follow-up study conducted in the Breast and Prostate Cancer Cohort Consortium (BPC3) with 496 fatal cases of prostate cancer did not replicate these findings [149]. A smaller case-only study found suggestive associations for SNPs in *VDR*, *CYP27B1*, and *CYP24A1* with prostate cancer survival [150], but there was little overlap with the findings from the prior studies. These studies and one other [151] did not find evidence that SNPs specifically associated with serum 25(OH)D were significantly associated with fatal prostate cancer or prostate cancer prognosis.

A metaanalysis of 11 studies (seven with information on melanoma-specific survival) with 3137 melanoma patients from Europe and the United States found that the *GC* rs2282679 polymorphism, which was associated with lower 25(OH)D levels, was associated with increased melanoma-specific deaths but not overall survival [152]. One study investigating six *VDR* polymorphisms and melanoma outcomes did not find significant main effects with disease relapse or overall survival [118]. However, another study that assessed 38 *VDR* polymorphisms and melanoma survival, with 3566 cases and 254 melanoma-specific deaths, observed that eight SNPs had nominally significant associations, and one functional SNP that affects *VDR* protein expression (rs2239182) remained significant after correcting for

multiple testing [153]. A study of 305 melanoma patients assessed candidate SNPs in four vitamin D—related genes, including *VDR*, did not find an association with melanoma prognosis [154]. Recently, a comprehensive study in melanoma patients assessed 2669 SNPs in the vitamin D pathway and disease-specific survival. After replication, two SNPs, rs12512631 in *GC* and rs7850212 in *RXRA*, were significantly associated [155].

Candidate gene studies focused on *VDR* have found associations with breast cancer survival, but the results have not been consistent. Perna et al. assessed the association of four *VDR* variants with breast cancer survival in a sample of 498 patients and found that rs731236 (Taq1) was associated with prognosis; they did not find an association with the other three variants, including Fok1 [156]. A small study ( $n = 115$  cases) of the four common *VDR* variants found that the Fok1 FF genotype is linked to poor prognosis in African American women with breast cancer; no association was found for Taq1 or the other variants [157]. A more comprehensive study of 106 SNPs over eight vitamin D pathway genes, including *VDR*, found that five SNPs in *RXRA* and one SNP in *PLAUR* were associated with disease-free survival in 1029 patients with early-stage breast cancer; the association with several of the SNPs in *RXRA* with survival was modified by type of systemic treatment received [158].

*VDR* polymorphisms have been associated with better survival outcomes in both early-stage and advanced non—small-cell lung cancer (Fok1, Cdx2, Bsm1) [76,113,114,159]. A study based in China found that *VDR* Apa1 genotype was associated with different chemotherapy response in patients with advanced non—small-cell lung cancer [160].

More studies are needed to assess whether vitamin D—related genetic variants may modify the associations of vitamin D and cancer mortality. Only a few such studies exist, and the findings have not been consistent, making it difficult to draw conclusions. A study assessing vitamin D status, and *VDR* Fok1 or Bsm1, and colorectal cancer survival did not show evidence of interaction [147], whereas another study of colorectal cancer survival did find a significant interaction between the *VDR* SNP (rs11568820) and a *VDR* haplotype (GAGC), 25(OH)D levels, and CRC-specific mortality [81]. The BPC3 study mentioned previously did not find main effects of the SNPs but did observe suggestive interactions between SNPs in *GC* and *CYP2R1*, circulating 25(OH)D and the risk of fatal prostate cancer [149]. Of interest, several of the SNPs in these genes were associated with levels of circulating 25(OH)D. The risk of fatal prostate cancer was highest in those men who despite carrying alleles associated with higher 25(OH)D in the general population still had individually low circulating 25(OH)D levels. A

study of melanoma patients found that there was an increased risk of melanoma relapse in those with the *VDR* Bsm1 A allele in patients with low-circulating 25(OH)D levels only [118]. Finally, a study of 1514 participants found that a variant in *VDR* (rs7968585) modified the association of 25(OH)D and a composite clinical outcome (incident hip fracture, myocardial infarction, cancer incidence, and total mortality). This finding was further replicated through a metaanalysis of three independent cohorts [161].

Overall, the evidence for independent contributions of *VDR* genetic variants on cancer prognosis and mortality remains unclear. Initial findings could be false positives, particularly in light of multiple testing concerns and the inconsistent results between studies. Conversely, studies with smaller sample sizes could lead to false-negative findings, especially if they are underpowered to detect the more modest associations expected to be the case with more common genetic polymorphisms. Thus, it is crucial to replicate promising findings. Systematic metaanalyses or pooled data from cohort consortiums will be important to generate large enough sample sizes, especially to test specific cancer subtypes and the potential for interactions between genetic variants, vitamin D status, and cancers.

## 4.2 Gene expression

The bioavailability of 25(OH)D in target tissues could be mediated by the expression of vitamin D–related genes, and data on vitamin D–related gene expression and cancer mortality are emerging. Several vitamin D–related genes, including *CYP27B1*, *CYP24A1*, and *VDR*, have differential mRNA or protein expression in cancer, and this expression may be associated with tumor characteristics and prognosis, but more research is needed [162]. In general, higher *VDR* and *CYP27B1* and lower *CYP24A1* expression have been found to be associated with less aggressive or better cancer outcomes, but these findings are not conclusive [111,130,136]. Higher expression of the *VDR* in prostate tumor tissue has been associated with a 60% decreased risk of lethal cancer among men with prostate cancer [163]. Higher levels of *VDR* expression have been associated with more favorable tumor [164–167] and better survival in breast cancer [164,167,168] in some studies but not all [166,169]. A large study with over 1000 breast cancer patients and 271 deaths (130 breast cancer-specific deaths) over a median of 6 years of follow-up found that although *VDR* expression was inversely related to aggressive tumor characteristics, it was not associated with patient survival outcomes [166]. Another study of 718 women with invasive breast tumors found that positive *VDR*

expression was associated with both favorable tumor characteristics and lower risk of breast cancer mortality [168]. In lung cancer, higher *CYP27B1* expression was associated with better prognosis in non–small-cell lung cancer patients [170], high *CYP24A1* [171] was associated with poorer survival, and higher *VDR* [172] correlated with longer survival in lung adenocarcinoma. These changes in gene expression would be expected to correlate with better survival, if increased vitamin D signaling was beneficial, and decreased signaling was detrimental. In colorectal cancer, a study of 658 patients found that expression of *VDR* in tumor stromal fibroblasts was associated with better clinical outcomes (progression-free survival and overall survival) [173]. A study of 99 colorectal cancer patients found that higher *CYP24A* expression in tumor tissue was correlated with more aggressive tumors and worse overall and disease-free survival [174]. Brozyna et al. have conducted studies reporting that decreased *VDR*, *CYP27B1*, and *CYP24A1* expression were all related to markers of worse melanoma prognosis as well as survival [175–177].

## 5. Conclusions

Since 1980, the hypothesis that vitamin D influences cancer incidence or mortality has been of interest to many cancer researchers. Initial provocative studies were based mostly on ecologic data. In the recent three decades, a large number of studies have examined pre-diagnostic 25(OH)D in relation to cancer incidence and mortality, and some studies have examined 25(OH)D levels and prognosis in cancer patients. For cancer incidence, most studies based on 25(OH)D have not supported an association, except possibly for colorectal cancer. In addition, Mendelian randomization studies support that higher vitamin D status is associated with a reduced risk of ovarian cancer [178,179]. Other than for ovarian cancer, most Mendelian randomization studies have not supported an association of 25(OH)D with incidence of most cancers. RCTs, though limited to around 5 years of duration for the vitamin D intervention, have generally not supported a benefit of vitamin D supplementation on total cancer incidence, though evidence for different types of cancers has been limited.

Of more promise, the epidemiologic and supporting mechanistic and animal evidence indicate that vitamin D may have a role in reducing cancer mortality and cancer prognosis, especially in breast and colorectal cancer. The RCT data to date are not definitive, yet are consistent with an effect on cancer mortality. Overall, around a 15% reduction in total cancer mortality was observed in individuals, most without cancer at baseline, who were randomized to vitamin D and subsequently

followed for cancer mortality. The evidence is clearer for studies that use daily dosing of vitamin D rather than large dose bolus dosing. Intriguingly, a Mendelian randomization study found a statistically significant association between genetically low 25(OH)D levels and total cancer mortality, up to around 50 nmol/L, with no further benefit at higher levels [146]. Thus, an effect of vitamin D on cancer mortality and survival has received support and should be the focus of further study. However, the assumptions for non-linear Mendelian randomization may have been violated so findings for non-linearity require further confirmation [179A].

Although RCTs will provide the most definitive evidence, an ideal trial would be difficult to design as questions still remain about the dose response, the optimal level of 25(OH)D, what intakes of vitamin D would be required to achieve this level, and the most relevant timing of exposure. Some studies have not found a beneficial effect in later stage cancers, indicating that the relevant time period of exposure may be earlier on in disease development. But more studies are needed to determine if this is the case, and the relevant timing may differ by cancer or even cancer subtype. Beyond randomized trials, further large-scale observational studies would be useful. Studies are also needed to establish the role of modifying factors, such as vitamin D–related genetic variants, gene expression, or lifestyle factors.

Further, more research is warranted to examine if association of vitamin D and prognosis differs by cancer subtypes of disease [116,126]. It is important to note that molecular defects in the vitamin D pathway could affect response to vitamin D supplementation. For example, if a tumor loses its VDR or the ability to convert 25(OH)D to 1,25(OH)<sub>2</sub>D at some advanced stage, supplementation with vitamin D may not be efficacious at that point. Molecular defects may help us better understand why some cancers appear to be less sensitive to the actions of vitamin D and may suggest novel approaches. For example, in one study, high plasma 25(OH)D level was associated with lower risk of colorectal cancers that had an intense immune reaction but not in those without such a reaction [180]. A small study compared VDR expression and prognostic value in *BRCA1* mutated breast cancers versus sporadic breast cancer cases and found that VDR expression was detected in over 90% of triple negative *BRCA1* mutated breast cancer and was significantly (VDR:  $P < .001$ ) over-expressed in *BRCA1* mutated as compared with sporadic cancer cases. The data also suggested that VDR was more strongly associated with overall survival in *BRCA1* mutated cases [181].

In summary, according to the human studies to date, the influence of vitamin D on cancer progression and mortality may be a potentially fruitful avenue to pursue. It is still unclear whether the potential benefit for vitamin

D status on cancer mortality is in the prediagnostic stages by influencing tumor aggressive behavior, during treatment through positive interactions with therapies or in postdiagnostic stages by enhancing survival. Of course, these potential benefits are not mutually exclusive, and vitamin D could be acting at prediagnostic and postdiagnostic stages. The benefit of additional vitamin D is likely to be stronger in those with low levels (for example,  $<50$  nmol/L), but more study is needed. There is evidence of widely prevalent vitamin D deficiency in general and especially among those diagnosed with cancer; thus, the potential for public health impact of an intervention with vitamin D may be very large.

## 6. Summary points

- Vitamin D may reduce cancer incidence or mortality through various biologic mechanisms, which has stimulated many population-based studies of vitamin D status and cancer risk.
- Many epidemiologic studies have been conducted examining circulating 25(OH)D levels as well as other surrogates of vitamin D status and cancer risk.
- Higher circulating 25(OH)D levels have been associated with lower risk of colorectal cancer, but generally not other cancers.
- Higher circulating 25(OH)D levels have been associated with lower risk of cancer mortality and better prognosis in cancer patients. This is seen across a spectrum of cancer types.
- There have not been many RCTs that have specifically examined vitamin D supplementation for cancer risk or mortality. However, cancer incidence and mortality as a secondary endpoint has been reported in a number of RCTs of vitamin D.
- In metaanalyses of RCTs of vitamin D and cancer, vitamin D supplementation has generally not been associated with total cancer incidence, but it has been associated with about a 15% decrease in cancer mortality. This benefit is especially seen in trials that use daily dosing of vitamin D but not infrequent high-dose bolus protocols.
- Population-based genetic studies have been equivocal in support of a role of vitamin D and cancer.

# Antiproliferative and immunoregulatory actions of vitamin D derivatives on hematological malignancies: control of differentiation, proliferation, and cell death

George P. Studzinski<sup>1</sup>, Elzbieta Gocek<sup>2</sup>,  
Ewa Marcinkowska<sup>3</sup> and Michael Danilenko<sup>4</sup>

<sup>1</sup>Department of Pathology, New Jersey Medical School, Rutgers University, Newark, NJ, United States <sup>2</sup>Bioceltix S.A., R&D Department, Wroclaw, Poland <sup>3</sup>Laboratory of Protein Biochemistry, Faculty of Biotechnology, University of Wroclaw, Wroclaw, Poland <sup>4</sup>Department of Clinical Biochemistry and Pharmacology, Ben-Gurion University of the Negev, Beer Sheva, Israel

## OBJECTIVES

- Present a general overview of differentiation-inducing effects of vitamin D derivatives (VDDs) on myeloid leukemia cells.
- Describe the signal transduction pathways and transcription factors involved in VDD-induced differentiation of myeloid leukemia cells.
- Discuss the regulatory effects of VDDs on cell cycle, proliferation, and survival of myeloid leukemia cells and the underlying mechanisms of these effects.
- Review the effects on lymphoid cells and the immunomodulatory activity of VDDs.
- Discuss the findings from model and clinical studies of VDDs and their combinations with other anticancer agents in hematopoietic malignancies.
- Emphasize significance of basic and clinical research of VDDs in hematopoietic malignancies: from bench to bedside.

## 1. Differentiation of myeloid leukemia cells by vitamin D derivatives

The studies of vitamin D derivatives (VDDs) as differentiation agents originated in 1981 when Tatsuo Suda's Laboratory showed that exposure of M1 mouse myeloid leukemia cells in culture to 1,25(OH)<sub>2</sub>D<sub>3</sub> induces these immature cells to differentiate into functional macrophages [1]. This important finding was followed by many studies confirming that acute myeloid leukemia (AML) blasts, murine or human cells [2,3], differentiate in response to treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub>, 1,25(OH)<sub>2</sub>D<sub>2</sub>, or their synthetic analogs (collectively referred to here as VDDs). Also, several other types of neoplastic cells show similar responses, including colon cancer, breast cancer, prostate cancer, neuroblastoma, osteosarcoma, squamous cell carcinoma, and malignant melanoma [4–6]. It was also found that tissue stem cells and normally developing immature progenitor cells can be induced to differentiate by 1,25(OH)<sub>2</sub>D<sub>3</sub>, including skeletal muscle satellite cells [7] and myoblasts [8], epidermal stem cells [9], keratinocytes [10,11], and hematopoietic cell precursors [12–14].

It is apparent that VDDs are powerful differentiating agents that target diverse cell types, but the physiological role of  $1,25(\text{OH})_2\text{D}_3$  in development remains to be fully determined. Data from vitamin D receptor (VDR) knockout (VDR-KO) mice suggest that  $1,25(\text{OH})_2\text{D}_3$  has little impact on normal myelopoiesis, though T lymphocytes exhibited abnormal responses in this model [12]. However,  $1,25(\text{OH})_2\text{D}_3$  increases adult hematopoietic stem and progenitor cell (HSPC) production and function in the zebrafish model *in vitro* and *in vivo* and enhances *in vitro* expansion and differentiation potential of  $\text{CD}34^+$  HSPCs from human umbilical cord blood [15] and bone marrow [16]. Human HSPCs and myeloid precursors were reported to have lower VDR expression than fully differentiated monocytes [16]. Interestingly, analysis of the gene expression data obtained by Metzeler et al. [17] demonstrated that VDR mRNA levels are also lower in leukemic cells from patients with undifferentiated or immature AML subtypes (AML-M0-M2) compared with AML subtypes with features of monocytic differentiation (AML-M4-M5) [16]. VDR-KO mice showed increased numbers of quiescent hematopoietic stem cells (HSCs) and leukemia stem cells, increased self-renewal, and myeloid differentiation block [16].

The interpretation of many *in vitro* studies with normal immature cells may be clouded by the use of high concentrations of  $1,25(\text{OH})_2\text{D}_3$  in significant excess over its physiological levels. However, it can be argued that concentrations of  $1,25(\text{OH})_2\text{D}_3$  in specific tissue niches in which precursor cells differentiate can be higher than the concentrations found in the plasma, because these niches may possess the  $1\alpha$ -hydroxylase (CYP27B1) enzyme, which permits the final hydroxylation of 25-hydroxyvitamin  $\text{D}_3$  ( $25(\text{OH})\text{D}_3$ ) to produce active hormonal  $1,25(\text{OH})_2\text{D}_3$  [18,19] (see Chapter 9). Currently, most studies utilize low nanomolar concentrations of  $1,25(\text{OH})_2\text{D}_3$  [19–21], and in this way, a clearer assessment of the physiological role of  $1,25(\text{OH})_2\text{D}_3$  in normal differentiation will perhaps be achieved.

## 1.1 Differentiation and its markers

Markers by which differentiated phenotypes of various cell types can be recognized are summarized, and sample references are provided in Table 86.1. HL60 human myeloblastic leukemia cells cultured with varying concentrations of  $1,25(\text{OH})_2\text{D}_3$  ( $10^{-10}$  to  $10^{-7}$  M for 1–7 days) differentiate morphologically and functionally first toward monocytes then to macrophages. This is recognized by expression of CD14 (a coreceptor for bacterial lipopolysaccharide, cell surface marker of early monocytic differentiation) and the

cytoplasmic enzyme nonspecific esterase (NSE)/monocyte-specific esterase (MSE), then by expression of CD11b (alpha subunit of CR3 integrin, cell surface marker of monocyte/macrophage, and granulocyte differentiation). At this stage, AML cells with monocyte/macrophage phenotype become adherent to solid surfaces, develop pseudopodia, reduce nitroblue tetrazolium (NBT), and develop the ability to phagocytose particles [22,23]. It may be speculated that macrophage-like differentiation of AML cells may also reduce leukemia-induced bone loss, since it was shown that activated bone marrow  $\text{CD}11b^+$  monocytes/macrophages stimulate osteogenesis by promoting differentiation of mesenchymal stem cells into osteoblasts [24,25].

Abnormal immature white blood cells (leukemic blasts) from AML patients also respond to VDDs when cultured *in vitro*. They frequently undergo at least partial monocytic differentiation as assessed by CD14 and CD11b expression, NBT reduction, morphology, and phagocytic ability, and their clonal growth is often inhibited [26,27]. However, there can be differences between AML cells in continuous culture and AML blasts in primary culture. For instance, it was reported that several samples of leukemic blasts, including those that had a deletion of chromosome 7, differentiated toward monocytes when cultured with  $1,25(\text{OH})_2\text{D}_3$ , but the leukemic blast samples with mutations of FLT-3 (internal tandem duplication or missense mutation) did not differentiate under similar conditions [21]. Conversely, established AML cell lines with FLT-3 mutations can differentiate in response to VDDs [28,29], suggesting that culture conditions can alter the response to VDDs. Alternatively, the general mutational landscape, rather than one identified mutation, may determine the susceptibility of the cells to VDD-induced differentiation.

## 2. Signaling and execution of monocytic differentiation induced by VDDs

### 2.1 Activation of VDR as the initial VDD-induced signal for differentiation of AML cells

Cells that differentiate when exposed to  $1,25(\text{OH})_2\text{D}_3$  usually express VDR [117,118]. VDR belongs to the superfamily of nuclear receptors that are ligand-activated transcription factors. After ligation of  $1,25(\text{OH})_2\text{D}_3$ , VDR becomes stabilized [119], then forms a homodimer or a heterodimer with retinoid X receptor alpha ( $\text{RXR}\alpha$ ), and translocates from the cytosol to the cell nucleus [120]. Then, the dimeric complex binds to the vitamin D response elements (VDREs) located in the promoter regions of the target genes (see Chapters 10–12).

**TABLE 86.1** Examples of cellular models of differentiation induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDDs

Differentiation marker	Known features	Comments	References

<sup>a</sup>Morphologic changes can be recognized in many forms of differentiation.

Recent findings obtained using next-generation sequencing (NGS) approaches, e.g., chromatin immunoprecipitation sequencing (ChIP-seq), in various cell types, including THP-1 human monocytic leukemia cells have expanded this classical scheme of VDR action to more complex epigenome-, genome-, and transcriptome-wide models [121–124]. In particular, it has been demonstrated that unliganded VDR already binds to a limited number of persistent loci within accessible chromatin and may act as first contact points of 1,25(OH)<sub>2</sub>D<sub>3</sub> with the genome [124]. In THP-1 cells, stimulation with 1,25(OH)<sub>2</sub>D<sub>3</sub> leads to a substantial (up to 10-fold) increase in genome-wide VDR binding via support of pioneer factors, such as PU.1, CEBPα, or GABPα (reviewed in Ref. [125]). Moreover, PU.1 showed a far more frequent colocation with VDR than RXR, and only the minority of the VDR-binding sites contained classical VDREs, which are formed by direct repeats spaced by three nucleotides (DR3) and bind VDR-RXR heterodimers [126]. Using RNA-seq, it has been shown that 1,25(OH)<sub>2</sub>D<sub>3</sub> induces a rapid (2.5–6 h) upregulation of ~370 genes in HL60 cells [127] and ~520 genes in THP-1 cells [128]. Further bioinformatics analysis predicted that in THP-1 cells, ~75% of the early-responsive genes and ~60% of those responding at a longer time point (24 h) are primary VDR targets [124,128]. The relation of thousands of genomic VDR-binding sites to several hundred primary VDR target genes remains largely unclear (see Chapters 10–12).

VDR expression has been detected in various types of mammalian cells [118], such as normal and leukemic hematopoietic cells, or stromal cells from the bone marrow [129–131]. The cellular amount of VDR transcript and

protein varies among the tissues and cultured cell lines, ranging from a few copies per cell, up to several dozen copies per cell [132]. VDR is expressed in both myeloid and lymphoid cell lineages and can be detected in various types of white blood cells, such as monocytes, macrophages, neutrophils, lymphocytes, dendritic cells (DCs), and platelets [129,130,133,134]. Interestingly, circulating monocytes have higher levels of VDR than tissue macrophages [135], which represent a more advanced stage of VDD-induced differentiation. Mature DCs showed lower levels of VDR than immature DCs or monocytes [130]. The requirement of a functionally active VDR for the differentiating action of 1,25(OH)<sub>2</sub>D<sub>3</sub> was confirmed by the studies on normal blood progenitor cells from VDR-KO mice that failed to differentiate into monocytes/macrophages in response to 1,25(OH)<sub>2</sub>D<sub>3</sub> [12]. Moreover, studies on VDR-KO mice with truncated or unliganded VDR showed that myeloid DCs generated ex vivo from bone marrow progenitors develop and function normally [136].

A large number of myeloid leukemia cell lines, blocked at various stages of maturation, express mRNA for VDR, although at different levels [129,137]. The presence of VDR is strictly required for VDD-induced monocyte/macrophage differentiation of AML cells [138,139], as well as normal mononuclear spleen cells and myeloid stem cells [12,140]. For instance, transfection of VDR conferred differentiation responsiveness to 1,25(OH)<sub>2</sub>D<sub>3</sub> in WEHI-3B D<sup>+</sup> murine myelomonocytic cells, which lack inducible VDR expression [138]. In VDR knockout mice, the phorbol ester 12-O-tetradecanoylphorbol-13-acetate (TPA), but not 1,25(OH)<sub>2</sub>D<sub>3</sub> [12] or 19-nor-1,25-dihydroxyvitamin D<sub>2</sub>

(paricalcitol) [140], induced differentiation of bone marrow-committed myeloid stem cells to monocytes/macrophages, which indicates the requirement of VDR for 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced monocyte/macrophage differentiation. These findings are supported by the fact that CRISPR/Cas9-mediated VDR-KO in THP-1 cells led to a complete loss of 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced gene regulation, indicating that transcriptome-wide effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> were entirely mediated by VDR [128]. The sensitivity of AML cells to VDD-induced differentiation depends on VDR protein levels. Cells with low initial level of VDR are resistant, but this may be overcome when VDR is upregulated by other compounds, such as *all-trans* retinoic acid (ATRA) [137]. Moreover, initial level of VDR protein can be elevated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [120]. In addition, MEG-01 human megakaryoblastic leukemia cells matured to megakaryocytes by TPA showed increasing VDR expression [141]. Inhibitors of MEK1/2 (PD98059) and PI3K (LY294002) reduced 1,25(OH)<sub>2</sub>D<sub>3</sub>-stimulated VDR upregulation and nuclear translocation, suggesting the involvement of MAP and PI3K kinases in these events [120]. The essential role of the p38 and JNK stress pathways and the downstream transcription factor activator protein-1 (AP-1) in upregulation of VDR expression was demonstrated in breast cancer cells [142]. Activation of the transcription factor nuclear factor erythroid 2-related factor 2 (NRF2) has also been shown to result in VDR upregulation in AML cells [143,144].

The classical paradigm of 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling is that the gene expression-modulating actions of VDR-RXR heterodimers transmit the differentiation signals to basal transcription machinery by interacting with VDRE sequences of the genome [145], and details are described in greater detail in Chapters 10–12. In an outline, a large assortment of nuclear receptor coactivators, such as DRIP/mediator and SRC/p160 and corepressors (e.g., SMRT and N-CoR) has been identified, which provides positive or negative regulation of the VDR transcriptional activity [146,147]. In addition to the “classic” VDRE sequences that transactivate vitamin D-responsive gene transcription, the “negative” VDREs have also been characterized that inhibit transcription of certain genes, e.g., parathyroid hormone gene [148]. Interestingly, in myeloid leukemia cells, promyelocytic leukemia zinc finger (PLZF), and the chromosomal translocation products, promyelocytic leukemia-retinoic acid receptor alpha (PML/RAR $\alpha$ ) and PLZF/RAR $\alpha$  also repress the differentiating action of VDR by binding and sequestering the VDR [149,150].

How the initial VDD-induced gene expression leads to the acquisition of a new functional phenotype, i.e., differentiation, is one of current mysteries, as among the multiple known direct target genes of VDR [128] only a few have been linked to the differentiating actions of

1,25(OH)<sub>2</sub>D<sub>3</sub> in tissues other than bone. In myeloid cells, these include CD14 [32,151], heterodimeric cell surface receptors, comprised of one  $\alpha$  subunit (CD11a, CD11b, or CD11c) and a common  $\beta$ -chain (CD18) [151], p21<sup>Cip1</sup> [151–153], as well as KSR1 and KSR2 [154,155]. Recent studies have demonstrated that 1,25(OH)<sub>2</sub>D<sub>3</sub> regulates the expression of multiple transcription factors in AML cells [127,128]. For instance, among the genes differentially expressed by 1,25(OH)<sub>2</sub>D<sub>3</sub> in THP-1 cells and predicted to be primary VDR targets, 47 were found to code for transcription factors [128]. In this context, the monocyte-like differentiation of HL60 cells treated with 1,25(OH)<sub>2</sub>D<sub>3</sub> may require AP-1 complexes, which bind to the TPA-responsive element (TRE) of the promoter region in human VDR [156]. However, with regard to differentiation of most cell types, the links from VDR-initiated events to the downstream targets of 1,25(OH)<sub>2</sub>D<sub>3</sub> still need to be found.

## 2.2 Differentiation signaling pathways activated by VDDs in AML cells

Exposure of hematopoietic cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> controls hundreds of genes, including those responsible for the regulation of cellular proliferation, differentiation, apoptosis, and angiogenesis [157], also reviewed in Ref. [158]. Using a genome-wide analysis of VDR-binding sites in THP-1 human monocytic leukemia cells, 2340 such sites were identified. Of those, 1171 and 520 occurred uniquely with and without 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment, respectively, while 649 were common. Ligand treatment revealed 638 1,25(OH)<sub>2</sub>D<sub>3</sub> target genes associated with immunity and signaling [159]. The genes CD14 and thrombomodulin (THBD) are upregulated primary vitamin D targets and were found to be suitable markers for vitamin D signaling in peripheral blood mononuclear cells and adipose tissue of individuals supplemented with vitamin D<sub>3</sub> [32]. The authors suggested that these biomarkers allow the classification of patients into those who may benefit from vitamin D<sub>3</sub> supplementation and others who may not. Modulation of these genes by 1,25(OH)<sub>2</sub>D<sub>3</sub> may not always be a direct effect on transcription of target genes but can reflect the entire process of differentiation associated with a series of interacting transcription factors. This and some highlights of the following discussion are illustrated in Fig. 86.1 and summarized in Table 86.2.

## 2.3 Protein kinase C signaling

A number of early studies linked several isoforms of protein kinase C (PKC) to differentiation [160]. Following the observation by Martell, Simpson, and Taylor [161] that treatment of HL60 cells by

**FIGURE 86.1** The MAPKs pathways that are upregulated by  $1,25(\text{OH})_2\text{D}_3$  in AML cells. The ERK and JNK pathways have positive effects on differentiation [183,251], while the p38 MAPK pathway may have a dual effect on differentiation. Several lines of evidence demonstrate that p38 $\alpha$  and p38 $\beta$  have an inhibitory effect on monocytic, but not granulocytic differentiation of HL60 cells [606,654], while p38 $\gamma$  and p38 $\delta$  may positively modulate monocytic differentiation of these cells [655].  $1,25(\text{OH})_2\text{D}_3$  can amplify the RAF-MEK-ERK pathway by direct transcriptional upregulation of kinase suppressor of RAS-1 (KSR1) [154], which acts as a scaffold that coordinates signaling along the RAS/ERK signaling module [656] or as an active kinase that phosphorylates c-RAF [657]. KSR2, a close homolog of KSR1 that is also directly upregulated by  $1,25(\text{OH})_2\text{D}_3$  [155], may have a similar role in the activation of the RAF-MEK-ERK pathway [658]. Also shown is the potential role of the AP-1 transcription factor, which acts as an intermediary positive effector of  $1,25(\text{OH})_2\text{D}_3$  signals by upregulating the expression of VDR [37]. Although only c-JUN and c-FOS are illustrated here, AP-1 can have other, interchangeable components. B-RAF has been shown to activate JNK, perhaps as a homodimer or a heterodimer with c-RAF (aka RAF-1) [464].

$1,25(\text{OH})_2\text{D}_3$  increases cellular TPA receptors, which implies increased PKC abundance, Hannun's laboratory showed that  $1,25(\text{OH})_2\text{D}_3$  increases the mRNA for isoforms  $\alpha$  and  $\beta$  of PKC in these cells [162]. These results were duplicated in many other laboratories, and PKC inhibitors or antisense oligonucleotides to this enzyme were demonstrated to interfere with  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation [163], further implying a role for at least some isoforms of PKC in differentiation induced by  $1,25(\text{OH})_2\text{D}_3$ . If its role could be established, PKC would provide an important regulatory element in a logically pleasing sequence of events that lead from an exposure of a cell to  $1,25(\text{OH})_2\text{D}_3$  toward differentiation. First, the lipid-soluble  $1,25(\text{OH})_2\text{D}_3$  may interact with cell membrane lipids or activate membrane-associated phospholipases [164] directly or through the still elusive membrane receptor, to generate a phospholipid second messenger, such as inositol 1,4,5-triphosphate ( $\text{IP}_3$ ) and 1,2-diacylglycerol (DAG).  $\text{IP}_3$  then releases calcium from the endoplasmic reticulum and thus promotes an increase in intracellular calcium ( $[\text{Ca}^{2+}]_i$ ).  $\text{Ca}^{2+}$  influx mediated by store-operated channels was also found to contribute to  $[\text{Ca}^{2+}]_i$  elevation in  $1,25(\text{OH})_2\text{D}_3$ -treated HL60 cells [165]. As the result of raised  $[\text{Ca}^{2+}]_i$  and DAG concentrations, several PKC isoforms can be activated [166,167], and the signal can be propagated further by

activating regulators of other signaling pathways, such as the mitogen-activated protein kinase (MAPK) pathway. Known examples of such links are the phosphorylation of c-RAF by PKC $\alpha$  in chick myoblasts [168] and the translocation of MAPK ERK1/2 to the nucleus in HL60 cells [169]. Differentiation of HL60 cells in response to  $1,25(\text{OH})_2\text{D}_3$  is accompanied by increased levels of PKC- $\beta$ , and this differentiation can be inhibited by a specific PKC inhibitor, chelerythrine chloride [170]. Other potential roles of PKC in  $1,25(\text{OH})_2\text{D}_3$  signaling are the regulation of VDR [171] and a major VDD-metabolizing enzyme, 24-hydroxylase (CYP24A1) [172,173] by PKC activation.

However, several major difficulties have so far precluded a full assessment of the role of PKC activity in differentiation. These include its presence in multiple isoforms with overlapping properties, and the fact that full inhibition of cellular PKC activity is usually incompatible with cell survival.

## 2.4 PI3-K/AKT/mTOR pathway

Participation of the phosphoinositide 3-kinase (PI3-K) pathway in VDD-induced monocytic differentiation was first noted by Hmama et al. by the finding that antisense

oligonucleotides against PI3-K abrogate CD14 expression in THP-1 and HL60 cells, as well as in normal monocytes [174]. More recent reports include the observation that in HL60 cells, the PI3K inhibitor LY294002 blocks 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced increases in NBT reduction, MSE activity [175], and differentiation [176]. Furthermore, the PI3-K/AKT pathway appears to promote cell cycle progression in HL60 cells within 48 h of exposure to 1,25(OH)<sub>2</sub>D<sub>3</sub> [177]. Also, in HL60 cells, PI3-K inhibitors can synergize with 1,25(OH)<sub>2</sub>D<sub>3</sub> to induce cell cycle arrest, and this is associated with a synergistic upregulation of the p27<sup>Kip1</sup> cyclin-dependent kinase inhibitor, as illustrated in Fig. 86.2 [177]. It is possible that this effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on cell proliferation contributes to the survival enhancing effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> and other VDDs in AML cells [178]. Interestingly, 1,25(OH)<sub>2</sub>D<sub>3</sub> and the AKT inhibitor MK-2206 were found to synergistically induce apoptosis in steroid-resistant T-ALL cells [179].

In addition, treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> or its synthetic analog 21-(3-methyl-3-hydroxy-butyl)-19-nor D<sub>3</sub> (Gemini-19-nor) for 4 days induced the expression of PTEN, which could block the PI3-K/AKT pathway, resulting in differentiation, cell death, or inhibition of growth of HL60 cells [180]. The role of this pathway in VDD-induced differentiation was further explored by the use of everolimus (aka RAD001), a rapamycin analog that inhibits AKT/mTOR complex-1 (mTORC1) signaling. It was found that everolimus potentiates the effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> on the differentiation and proliferation of U937 cells [181]. More recently, it has been reported that the rapamycin-insensitive mTOR complex-2

(mTORC2) can function as an upstream regulator of the PI3-K/ATK pathways in HL60 cells induced to differentiate by 1,25(OH)<sub>2</sub>D<sub>3</sub> and that silencing of the rapamycin-insensitive companion of mammalian target of rapamycin (RICTOR) by siRNA suppressed the ability of 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated cells to reduce NBT [175]. Interestingly, 1,25(OH)<sub>2</sub>D<sub>3</sub> was shown to induce both the expression of CD14 and activation of the mTOR signaling pathway in U937 and THP-1 cells differentiated into macrophages by the PKC activator TPA [182]. This was prevented by mTOR inhibitors PP242 and Torin1 or by siRNA-induced silencing of either regulatory-associated protein of mTORC1 (Raptor) or RICTOR, indicating that both mTORC1 and mTORC2 are important for 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced expression of CD14 in myeloid leukemia cells. The potential of VDD-regulated intracellular signaling, including the PI3-K/AKT pathway as targets for myeloid leukemia therapy, has been reviewed [158].

## 2.5 MAPK pathway

This pathway may be crucial for VDD-induced differentiation of AML cells. Exposure of either HL60 or NB4 cells to differentiation-inducing concentrations of VDDs causes activation and nuclear translocation of the ERK, JNK, and p38 MAPK proteins [37,169]. In these experiments, 1,25(OH)<sub>2</sub>D<sub>3</sub> stimulated the transient (10 min–48 h) phosphorylation of ERK1/2 in HL60 cells. After 24 h, the level of phosphorylated ERK decreased to basal levels, while differentiation

**FIGURE 86.2** Regulators of p27<sup>Kip1</sup> expression during G1/S progression at both translational and posttranslational levels. The main form of regulation of the p27<sup>Kip1</sup> protein levels in most mammalian cells is proteasome-dependent degradation, as illustrated in the lower part of this figure. In proliferating cells, p27<sup>Kip1</sup> is phosphorylated by several kinases (originally proposed to be CDK2 and ERKs [378]), then ubiquitinated by SKP2 [386], which leads to its degradation. In addition, p27<sup>Kip1</sup> can be destabilized by phosphorylation on non-CDK sites [390–392] or by cytoplasmic localization through binding to proteins such as 14-3-3 [659,660]. However, there is an important contribution of transcriptional control. For instance, in myeloid cells, translation of p27<sup>Kip1</sup> mRNA can be inhibited by miR-181a, resulting in G1/S block [20,393]. Conversely, upregulation of p27<sup>Kip1</sup> expression can be transcriptionally activated by the forkhead transcription factors (TFs), such as AFX (FOXO4) [381,382], as well as the AP-1 transcription factor (not shown here) [384]. The FOXO activity is under the control of the PI3-K/AKT pathway, which in turn is regulated by the tumor suppressor PTEN, important in human malignancies. In this figure, the double helix shape in the lower part represents the human genome, as the precise transcription start site of p27<sup>Kip1</sup> has not been clearly identified. Various start sites for this gene have been described, and the major site was found to produce a GC-rich 5'-UTR of 472 nucleotides [385,661,662]. The MEK5/ERK5 pathway and the direct ERK5 downstream target transcription factor MEF2C [190] are upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [33]. Inhibition of MEK5/ERK5 [192] or the upstream activator COT1/TLP2 kinase [191] leads to upregulation of p27<sup>Kip1</sup> and proliferation/cell cycle arrest in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated AML cells.

continued over an additional 48 h [183]. In another report, phosphorylated c-RAF, MEK1/2, and ERK1/2 were detected in HL60 cells at least 72 h after treatment with  $5 \times 10^{-9}$  M 1,25(OH)<sub>2</sub>D<sub>3</sub> [184]. Further, PD98059, an ERK1/2 inhibitor, blocked the 1,25(OH)<sub>2</sub>D<sub>3</sub>-stimulated differentiation of HL60 cells [184]. In addition to inducing long-term MAPK activation, VDDs are also capable of rapid stimulation of this and other signal transduction pathways. This is thought to be mediated by caveolae-associated nuclear VDR, probably in conjunction with nonnuclear 1,25(OH)<sub>2</sub>D<sub>3</sub> receptors, such as membrane-associated rapid response steroid (MARRS) or protein disulfide isomerase family A member 3 (PDIA3), and caveolin-1 (reviewed in Refs. [185–188]. For instance, 1,25(OH)<sub>2</sub>D<sub>3</sub> was found to markedly increase phospho-ERK1/2 levels in HL60, NB4, U937, and THP-1 cells following 60 min of incubation [189]. This effect was blocked by pharmacological antagonists of nuclear VDR and did not appear to require heterodimerization with RXR $\alpha$ . Inhibitors of the SRC tyrosine kinase, RAS, RAF, and PKC $\alpha$  also abrogated the 1,25(OH)<sub>2</sub>D<sub>3</sub>-stimulated increase in ERK kinase activity. These results support the notion that the

plasma membrane-associated nuclear VDR can mediate rapid nongenomic 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling in AML cells, SRC, and PKC being upstream regulators of the MAPK pathway [189]. Other studies have also demonstrated that PKC is an upstream regulator of the RAF/MEK/ERK pathway [168,169].

A less well-studied MAPK is ERK5. This kinase overlaps the functions of ERK1/2 in cell proliferation and survival, functioning in a manner distinct from ERK1/2 in human AML cells induced to differentiate by 1,25(OH)<sub>2</sub>D<sub>3</sub>. Using inhibitors of ERK1/2 and of MEK5/ERK5 at concentrations specific for each kinase in HL60 and U937 cells, it was found that ERK5 and its direct downstream target transcription factor MEF2C [190] are upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> in parallel with monocytic differentiation [33]. Earlier experiments in these cell lines demonstrated that ERK5 phosphorylation (activation) by an exposure to 1,25(OH)<sub>2</sub>D<sub>3</sub> and, particularly, by its combination with the plant antioxidant silibinin, was, at least partially, dependent on the activity of an oncogenic COT1/TLP2 kinase [191]. Notably, inhibition of either COT1/TLP2 [191] or MEK5/ERK5 [192] resulted in upregulation of p27<sup>Kip1</sup>

and proliferation/cell cycle arrest in  $1,25(\text{OH})_2\text{D}_3$ -treated AML cells. This  $1,25(\text{OH})_2\text{D}_3$ -regulated pathway is illustrated in Fig. 86.2. Interestingly, the transcription factor C/EBP $\beta$  was found to be positively regulated, while C/EBP $\alpha$  was negatively regulated by ERK5 upon cell exposure to  $1,25(\text{OH})_2\text{D}_3$  [190,192].

Upstream from ERKs in the MAPK pathway are kinase suppressors of RAS-1 and RAS-2 (KSR1-2), which phosphorylate c-RAF and act as scaffolds, and increase the efficiency of signaling by c-RAF [154,155]. These two genes have an upstream promoter containing a functional VDRE motif. Knockdown of KSR-2 blocked  $1,25(\text{OH})_2\text{D}_3$ -induced myeloid differentiation. Signaling by RAF-1 is required for the later stage of  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation and requires p90 RSK, which is either directly or indirectly phosphorylated by c-RAF [193].

## 2.6 ERK5 and VDD-induced progression of monocytic to macrophage differentiation

As described before, a prolonged exposure of cultured AML cells to VDDs results first in the emergence of monocytic phenotype (CD14 and NSE positivity), then macrophage-like features (increased CD11b expression, characteristic morphological changes). This can be accelerated by the addition of a retinoid to the VDD, as evidenced by the appearance of M2 macrophage marker genes, such as CD163, ARG1, and IL-10, increased surface CD163 expression, and IL-10 protein secretion [194]. Mechanistically, other data support the hypothesis that ERK5 negatively regulates the expression of M-CSFR, and thus has a restraining function on macrophage differentiation, resulting in a prolonged phase of monocytic phenotype [50]. This may be one example of the complexity of differentiation programs, which are currently being apprehended more fully.

## 2.7 WNT/ $\beta$ -catenin signaling

The WNT/ $\beta$ -catenin signaling pathway has tied to both  $1,25(\text{OH})_2\text{D}_3$  signaling and leukemia development. This pathway is well established in the regulation of development and differentiation, and its dysregulation has been demonstrated in a number of neoplastic diseases including leukemias and lymphomas [195–198]. WNT ligands bind to a receptor complex containing one of the Frizzled proteins (FZD) and either LDL receptor-related protein 5 or 6 (LRP5/6), promoting the eventual translocation of the transcriptional activator  $\beta$ -catenin into the nucleus [197,198]. The activation of the noncanonical ( $\beta$ -catenin-independent) WNT pathway involves additional coreceptors, such as the receptor Tyr kinase-like orphan receptor family (ROR1

and ROR2), the receptor tyrosine kinase RYK, and the protein Tyr kinase 7 (PTK7). The noncanonical signaling is mediated by small GTPases RhoA, Daam1, and ROCK, acting on cytoskeleton remodeling, or by phospholipase C/PKC, JNK, and nuclear factor of activated T cells (NFATs), acting on transcriptional activity [198]. WNT signaling is involved in the regulation of normal hematopoiesis and the specification of hematopoietic differentiation in hematopoietic stem cells [196,198,199].

Studies demonstrated that VDDs exert inhibitory effects on WNT/ $\beta$ -catenin signaling through both direct and indirect mechanisms [200,201]. In colon cancer cells [197], the primary direct inhibitory mechanism is the binding of  $1,25(\text{OH})_2\text{D}_3$ -bound VDR to  $\beta$ -catenin, which inhibits at least some WNT/ $\beta$ -catenin transcriptional activity [202]. The indirect mechanisms involve VDR-regulated gene products; primarily the induction of DKK-1, which binds to LRP5/6 and prevents the initiation of the WNT signaling cascade [200], and also the upregulation of E-cadherin, which binds to  $\beta$ -catenin in the cytoplasm and reduces its translocation into the nucleus [55]. The  $1,25(\text{OH})_2\text{D}_3$  analog calcipotriol was found to target LRP6 through transcriptional upregulation of LDL receptor adaptor protein 1 (LDL-RAP1) to inhibit WNT signaling in pancreatic cancer [203]. Interestingly, it was demonstrated that the nongenomic  $1,25(\text{OH})_2\text{D}_3$  pathway and the noncanonical WNT5a pathway can interact through the shared components of their membrane  $1,25(\text{OH})_2\text{D}_3$  and WNT receptors to regulate the balance between proliferation and differentiation of chondrocytes [204].

The dysregulation of WNT/ $\beta$ -catenin signaling has been shown to contribute to the development of myeloid and lymphocytic leukemias [196]. The products of balanced translocations have been shown to activate the WNT signaling pathway in AML cells [205], and the loss of  $\beta$ -catenin disrupts the expression of multiple oncogenes in AML and reduces the incidence of leukemia cell self-renewal [196,206]. WNT/ $\beta$ -catenin signaling upregulates the transcription of the RUNX1-ETO fusion gene that is created by the reciprocal 8:21 translocation in AML cells and contributes to the neoplastic phenotype [207]. The WNT pathway is also involved in the generation and maintenance of chronic myelogenous leukemia (CML) in vivo [196]. Importantly from a therapeutic perspective,  $1,25(\text{OH})_2\text{D}_3$  was shown to suppress the development of breast cancer through suppressing  $\beta$ -catenin activity [208], and the activation of WNT/ $\beta$ -catenin signaling was shown to be important in the acquisition of drug resistance in acute leukemia cells in the bone marrow microenvironment [209]. Also,  $1,25(\text{OH})_2\text{D}_3$ /VDR signaling was reported to suppress WNT/ $\beta$ -catenin signaling in melanoma, and this was associated with less metastatic disease and stronger host immune responses [210].

## 2.8 JAK/STAT pathway

Characterization of this pathway may lead to advances in the understanding of leukemogenesis and may have potential for improved therapy of hematological neoplasms [158,211]. Particularly, constitutive activation of STAT5, ERK, and AKT in the leukemic stem cell (LSC) population of bone marrow–derived blasts from patients with AML was associated with poor survival and failure to achieve remission [211]. A phase I trial showed that ruxolitinib, a JAK-1 and JAK-2 inhibitor currently approved for patients with severe myelofibrosis, can induce objective responses in patients with chronic myelomonocytic leukemia [212]. It has been shown that  $1,25(\text{OH})_2\text{D}_3$  and its analog EB1089 selectively inhibit IL-2-induced STAT1 and STAT3 phosphorylation and inflammatory cytokine production in NK cell large granular lymphocyte leukemia (NK-LGLL) cells characterized by hyperactivated JAK/STAT pathway [213,214]. However, AML cells with mutations, which lead to constitutive activation of STAT1/STAT5, have low expression of VDR and are not responsive to VDDs [215,216]. On the other hand, a recent study has demonstrated that coordinated activation of the JAK-STAT, p38 MAPK, and NF- $\kappa$ B pathways is necessary for the synergistic upregulation of CYP27B1 expression by IFN $\gamma$  and CD14/TLR4 binding in monocytes. This upregulation correlated with increased  $1\alpha$ -hydroxylase activity and production of  $1,25(\text{OH})_2\text{D}_3$  [217]. Moreover, this and previous studies showed that  $1,25(\text{OH})_2\text{D}_3$  does not downregulate the induced  $1\alpha$ -hydroxylase in monocytes [218]. This is in a striking contrast to kidney cells, in which  $1,25(\text{OH})_2\text{D}_3$  is a negative regulator of CYP27B1 expression [219].

## 3. Transcription factors in VDD-induced differentiation

In addition to VDR, which is directly activated by VDDs and heterodimerizes with a member of RXR family to induce transcription of VDRE-containing genes, several ubiquitous transcription factors also appear to be involved, perhaps in a contributory way, in VDD-induced differentiation (Table 86.2). These may act by interacting with the adjacent VDREs [220,221], by upregulating VDR expression through its promoter region [222–224], by complexing with other transcription factors [221,225,226], and in other ways that remain to be elucidated. On the other hand, some transcription factors [227,228] were found to repress VDR expression and, thus, to attenuate  $1,25(\text{OH})_2\text{D}_3$  signaling. Besides VDR, certain vitamin D metabolites, e.g.,  $20,23(\text{OH})_2\text{D}_3$  or its precursor  $20(\text{OH})\text{D}_3$ , may activate additional ligand-dependent transcription factors, such as aryl

hydrocarbon receptor [229], thereby expanding the repertoire of cellular regulatory pathways affected by VDDs.

## 3.1 Transcription factors involved in developmental myeloid differentiation

During differentiation of HSPCs, specific transcription factors are expressed at crucial developmental stages and regulate, positively or negatively, myeloid commitment of these precursors in both health and various diseases. Among the key regulators of early hematopoiesis are runt-related transcription factor 1 (RUNX1; also known as AML1), ETS variant transcription factor 2 (ETV2), and stem-cell leukemia factor (SCL; also known as TAL1) [230]. RUNX1 is essential for the formation of HSCs and hematopoietic progenitors via facilitated expression of critical regulators of the endothelial-to-hematopoietic transition (EHT), such as growth factor independent 1 (GFI1) and GFI1B [231]. The upregulation of RUNX1 during the EHT is responsible for the upregulation of PU.1/SFPI1, a master regulator of myelopoiesis and B cell development [231,232]. Following PU.1, other transcription factors are upregulated during myelopoiesis, including CCAAT/enhancer binding protein (C/EBP) $\alpha$ , followed by C/EBP $\beta$  and C/EBP $\epsilon$ , growth factor independent 1 (GFI1) and interferon-regulatory factor 8 (IRF8; also known as ICSBP). Macrophage differentiation depends on PU.1 and IRF8. GFI1, C/EBP $\alpha$  and C/EBP $\epsilon$  are crucial for neutrophil differentiation. On the other hand, IRF8 blocks C/EBP $\alpha$  activity to suppress the neutrophil differentiation program [233]. The aforementioned transcription factors regulate the expression of many myeloid genes, such as those encoding receptors for M-CSF, G-CSF, and GM-CSF [234,235]. GATA-1 is induced by IL-4 during dendritic cells differentiation from monocytes [227].

Aged human HSCs have been shown to have myeloid-biased differentiation potential compared with young HSCs. This was accompanied by upregulation of genes associated with cell cycle, myeloid lineage specification, and myeloid malignancies [236]. Particularly, dysregulation of the monocyte/macrophage differentiation primary response transcription factor EGR-1 in aged HSCs was linked to the reduction of G2/M phase of the cell cycle and induction of quiescence regulators, such as JUNB, BTG antiproliferation factor 2 (BTG2), and nuclear receptor subfamily 4 group A member 1 (NR4A1) [237]. Chronic infection also results in increased myeloid differentiation of HSPCs, which leads to their depletion in the bone marrow. This differentiation effect was found to be induced by accumulated IFN $\gamma$  through activating the

basic leucine zipper ATF-like transcription factor 2 (Batf2) [238].

Several negative regulators of myeloid differentiation have been identified. For instance, the RNA-binding protein ZFP36L2 was found to interact with the 3' untranslated region of key myeloid maturation genes to promote their mRNA degradation and suppress terminal myeloid cell differentiation. Conversely, genetic inhibition of ZFP36L2 led to upregulation of several key monocytic/macrophage-associated genes (e.g., CD14, CSF1R, CEBPB, IL1B, and MMP9) and downregulation of genes associated with leukemia stem cell signatures [239]. Another example is the homeobox transcription factor HB9 whose aberrant expression is a molecular hallmark of infant t(7;12) (q36;p13) AML [240]. HB9-transduced HSPCs underwent a profound differentiation arrest and accumulated at the megakaryocyte/erythrocyte progenitor stage in vivo [241]. High expression of Iroquois homeobox transcription factor 3 (IRX3) was shown to be associated with reduced myelomonocytic differentiation, and IRX3 knockdown induced terminal differentiation of AML cells [242]. Expression of mutant RUNX1 was found to enhance self-renewal and impair myeloid commitment of HSPCs. CEBP $\alpha$  expression was reduced in RUNX1 mutant-expressing cells, and reexpression of CEBP $\alpha$  partly restored differentiation [243]. In patient-derived AML blasts, increased occupancy of CTCF-binding factor (CTCF), which regulates gene expression through chromatin organization, was found in DNA motifs for key myeloid transcription factors such as C/EBP $\alpha$ , PU.1, and RUNX1, and CTCF knockdown resulted in increased myeloid differentiation [244]. Leukemia-associated mutant cohesin complex proteins can also impair HSPC differentiation by controlling chromatin accessibility for key differentiation-related transcription factors [245]. Expression of the AML-associated chimeric transcription factor RUNX1-ETO in normal myeloid progenitor cells was shown to interfere with RUNX1 binding, leading to extensive chromatin reprogramming and differentiation block [246].

### 3.1.1 Activator protein-1 transcription factor

ERK and JNK pathways activate members of the FOS and JUN families, as well as some related proteins, which dimerize in various combinations to form the AP-1 transcription factor [247,248]. Thus, AP-1 can integrate and transmit signals transduced by the MAPK pathways previously discussed. Integrated analysis of epigenetic profiles, gene expression, and chromatin conformation data in purified leukemic blasts from multiple AML samples has shown that mutated components of the MAPK/AP-1 pathway form a prominent regulatory network in most of the AML subsets. Notably, the

expression of a dominant negative form of c-FOS in AML cells carrying t(8;21) translocation (Kasumi-1) and FLT3-ITD mutation (MV4-11) was sufficient to block cell growth in vitro and tumor formation in mice [249,250].

Several studies have shown that the expression of c-JUN is increased during the 1,25(OH) $_2$ D $_3$ -induced differentiation of human myeloid cells [156,251,252] and coordinates the occupancy of AP-1 sites and VDRE elements by their cognate transcription factors. This can provide a possible model for the reciprocal relationships between different cellular phenotypes and functional activities, such as those that occur during differentiation. For example, there is also evidence for functional cooperation between VDR and RAS-activated ETS transcription factors in 1,25(OH) $_2$ D $_3$ -mediated induction of the VDD-metabolizing enzyme 24-hydroxylase (CYP24A1) gene expression [253]. Liu and Freedman [220] conducted an extensive study of such transcriptional synergism between VDR and nonreceptor transcription factors and concluded that the functional basis for such synergism appears to be at the level of cooperative DNA binding.

AP-1 activation by 1,25(OH) $_2$ D $_3$  has been described in diverse differentiation systems. These include HL60 cells [156,254], colon cancer CaCo-2 cells [255], osteoblasts [256], keratinocytes [257], and breast cancer cells [142]. Interestingly, the pathways that signal AP-1 activation are apparently cell type and cell context specific. For instance, the p38 and JNK MAPK pathways cooperate to activate VDR by c-JUN/AP-1 in breast cancer cells [142], while in keratinocytes and HL60 leukemia cells, AP-1 activation is attributed to both the ERK and JNK pathways, e.g., in the presence of plant antioxidants [156,258,259].

The AP-1 complex has variable components, some of which can interact with the VDR transcriptional machinery. For instance, the exposure of the CML cell line RWLeu-4 to 1,25(OH) $_2$ D $_3$  inhibited their proliferation and enhanced the binding activity of the proto-oncogene JUN-D to the VDRE [260]. Exposure of HL60 cells to 1,25(OH) $_2$ D $_3$  upregulated expression of genes that code for the AP-1 complex including c-JUN, ATF-2, JUN-B, and FOS-B [156,261]. Moreover, 1,25(OH) $_2$ D $_3$  (10 $^{-7}$  M) induced within 6 h the expression of the subunits of the transcriptional coactivator, vitamin D receptor-interacting proteins (DRIP, also called thyroid hormone receptor-associated polypeptide; TRAP), in HL60 cells [262]. The DRIP complex plays a role in direct communication between the nuclear receptors and the general transcriptional machinery through direct interaction with RNA polymerase II [263]. DRIP knockdown-HL60 cells as well as murine TRAP220 $^{-/-}$  yolk sac hematopoietic progenitor cells are resistant to induction of differentiation by 1,25(OH) $_2$ D $_3$ .

Thus, the aforementioned examples show that AP-1 transcription factor appears to be an important integrator of converging differentiation pathways.

### 3.1.2 Specificity protein 1 transcription factor

The SP1, a 95–105 kDa protein, is ubiquitously expressed in growing cells, and, usually in combination with other factors, acts as a transcriptional activator of many housekeeping genes [264–269]. Its role in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation has been suggested in human myeloid leukemia cells. Specifically, the DNA binding of SP1 was found to be increased following an exposure of HL60 cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> [254,270], while in U937 cells, SP1 may participate in the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced expression of CD14 monocyte marker, which has several SP1-binding sites in its promoter [271], as well as the CD11b promoter [272]. It was also shown that upregulation of p27<sup>Kip1</sup> in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated U937 can be mediated by SP1 [273], as discussed in the following.

### 3.1.3 Master transcription factors

1,25(OH)<sub>2</sub>D<sub>3</sub> can induce master transcription factors of myeloid differentiation to regulate gene expression. For example, exposure of AML cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> induced the expression of PU.1 and IRF8 (e.g., Ref. [274]) but, in contrast, downregulated the expression of ETV7 (also known as TEL2), which is a member of the ETS family [275]. Interestingly, forced overexpression of ETV7 inhibited 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation. PU.1 knockdown has been shown to drive AML development, while its restoration triggers AML differentiation and clearance in vivo [276]. Notably, PU.1 suppression in differentiating AML cells can induce dedifferentiation and reacquisition of clonogenic and leukemogenic properties [276].

The activation of the master transcription factor, proto-oncogene c-MYC, is a typical feature of human leukemias and lymphomas (reviewed in Refs. [277,278]). The HL60 leukemia cell line is characterized by high levels of expression of c-MYC due to gene amplification [162,279]. Treatment of these cells with 1,25(OH)<sub>2</sub>D<sub>3</sub> results in a downregulation of expression of c-MYC associated with the induction of cell differentiation [280–282]. This suppression of c-MYC occurs at the transcriptional level [281–283]. A similar c-MYC downregulation was observed in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated head and neck squamous cell carcinoma (HNSCC) cells and primary keratinocytes, while the expression of the c-MYC antagonist MAD1/MXD1 was enhanced [282]. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> induced a rapid association of the VDR with c-MYC, suggesting that 1,25(OH)<sub>2</sub>D<sub>3</sub> may also control c-MYC stability [282]. 1,25(OH)<sub>2</sub>D<sub>3</sub> also upregulates the protein encoded by the homeobox gene HOXB4 that binds to the first exon/intron border

of c-MYC to prevent transcriptional elongation, a process dependent on activation of PKC-β [286]. Another homeobox gene, HOXA10, was found to be transcriptionally induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> through binding to the VDRE in the promoter during differentiation of U937 cells [285].

Exposure of HL60 cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> induces the expression of the proto-oncogene c-FMS, which encodes the receptor for M-CSF. It occurs in parallel with the induction of CD14 expression and a block of the cell cycle in the G0/G1 phase [286]. cDNA microarray analysis showed that at early times of VDD exposure, the putative oncogenes DEK and FLI1 were downregulated and the antiproliferative gene BTG1 was upregulated.

### 3.1.4 Other transcription factors that contribute to VDD-induced differentiation

Other transcription factors can be induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> in differentiating myeloid cells. For instance, high expression levels of PPARδ are detected in the AML cells with an AML-M5 (monoblastic) phenotype. Furthermore, the forced overexpression of PPARδ suppressed the 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated monocyte–macrophage differentiation [287]. Upregulation of PPARδ expression was found upon overexpression of the H2.0-like homeobox transcription factor (HLX) in zebrafish and human HSPCs. Pharmacological inhibition of PPARδ signaling relieved the HLX-induced myeloid differentiation block [288].

Increased expression of monocytic lineage transcription factor EGR-1 by 1,25(OH)<sub>2</sub>D<sub>3</sub> in myeloblastic HL60 cells (AML-M2) was shown to contribute to onset of the terminal phase of monocyte/macrophage differentiation [289]. Interestingly, EGR-1 levels were also increased by 1,25(OH)<sub>2</sub>D<sub>3</sub> in granulocyte-committed acute promyelocytic leukemia (APL; AML-M3) NB4 cells. Furthermore, GFI1, which promotes the granulocytic lineage, was upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> in HL60 cells and by ATRA in myelomonocytic (AML-M4/M5) U937 cells [290].

It has been documented that retinoic acid receptor α (RARα) is able to regulate expression of VDR in AML cells [224], and to much lower extent in normal human blood cells [291]. This regulation is quite complex, not fully understood, and depends on the levels of RARα protein in the cells. In cells with high levels of RARα protein, this unligated transcription factor inhibits the expression of VDR, while it upregulates VDR expression upon binding the ligand, ATRA. Interestingly, the regulation is opposite in those AML cells that have low levels of RARα protein [137,224].

Fusion proteins involving the RARα with either the PML or PLZF nuclear proteins can provide genetic markers of APLs. APL cells expressing PML-RARα fusion protein are sensitive to retinoid-induced

differentiation to granulocytes in the presence of ATRA. In contrast, forced expression of either PML-RAR $\alpha$  or PLZF-RAR $\alpha$  in either U937 or HL60 cells blocked their terminal differentiation after exposure to 1,25(OH) $_2$ D $_3$  [292]. Both PML-RAR $\alpha$  and PLZF-RAR $\alpha$  can bind to VDR in U937 cells and sequester VDR away from activation of its normal DNA targets [150]. Overexpression of VDR overcomes the block in 1,25(OH) $_2$ D $_3$ -stimulated differentiation caused by the fusion proteins. Of note, PLZF itself can interact directly with VDR, and overexpression of PLZF can inhibit the 1,25(OH) $_2$ D $_3$ -induced differentiation of U937 cells [149].

Undoubtedly, many other transcription factors, including C/EBP $\beta$ , contribute to 1,25(OH) $_2$ D $_3$ -induced differentiation of AML cells [128,293,294]. It has been reported that C/EBP $\beta$  isoforms are activated by phosphorylation by ERK [295] and by RSK [296], and interact directly with the promoter of one of the principal markers of monocytic differentiation - CD14 [297]. In myeloid leukemia cells, hematopoietic progenitors are unable to undergo granulocytic differentiation, as a result of various mutations, which alter the proper balance of transcription factor activity. Elevated expression of C/EBP $\beta$  induced by 1,25(OH) $_2$ D $_3$  allows the cells to bypass this block by switching the lineage of differentiation to monocyte-like cells instead of granulocytes [294].

Other transcription factors may also contribute to the eventual cell cycle arrest, and some of these will be discussed relative to cell cycle control. The important distinction between the transcription factors, which regulate the expression of new genetic programs, and those that control functions of the differentiated cells, is not easy to make at present.

## 4. Effects of VDDs on the cell cycle and proliferation of human leukemia cells

### 4.1 General features of the cell cycle

In general, the cell cycle and its regulation are extremely well conserved throughout the eukaryotic species. The consecutive progression through the G1, S, G2, and M cell cycle phases results in proliferation of eukaryotic cells (Fig. 86.3). DNA replication occurs during the S phase; chromosome separation (karyokinesis) takes place during the M phase and is followed by cell division (cytokinesis); G1 and G2 are gap or growth phases when molecules required for DNA replication or mitosis are synthesized. Cells that are not actively dividing may either be permanently removed from these cycling phases by terminal differentiation, senescence or apoptosis, or be temporarily arrested in a noncycling quiescent state known as G0 if the cells

have the G1 DNA content [298]. The basic cell cycle machinery consists of several cyclin-dependent kinases (CDKs) and cyclins that pair with each other, sometimes changing partners, to drive the cell toward and through mitosis [299,300]. CDKs are usually present throughout the cell cycle, while cyclin levels oscillate in a cell cycle-dependent manner. This basic arrangement occurs in all cells, despite the necessity for cell type specificity of proliferation control in multicellular organisms. The most studied target of cyclin/CDK activity is the retinoblastoma susceptibility protein (pRB); the phosphorylation of pRB is the principal mechanism regulating cell transit through G1.

Control of cell cycle transit is provided primarily by the regulation of cyclin/CDK activities, which occur in response to various internal and external cues. Importantly, cell cycle changes are also triggered in cells undergoing differentiation. A series of checkpoints control the traverse of the various cell cycle compartments [301]. Checkpoints may be simply defined as mechanisms that prevent cell cycle progression until a specific requirement has been met. Checkpoints operate in each phase of the cell cycle: pRB phosphorylation acts as a G1 checkpoint. Checkpoints control each phase of the cell cycle. pRB phosphorylation acts as a G1 checkpoint [302], and the CHK1 and CHK2 kinases act as S phase checkpoints in response to DNA damage [303]. Other regulators such as p53 have been shown to have importance in checkpoint control, though in hematopoietic malignancies, p53 is often inactivated by mutations. Interestingly, these regulators of cell cycle progression may also influence cellular decisions to differentiate in embryonic, normal adult, and transformed phenotypes [303,304]. The final result of the cell cycle traverse is usually a faithful replication and accurate partitioning of genetic information.

Differentiation can be considered to be, in essence, a persistent change in the pattern of previously expressed genes, which results in new functional capabilities of the differentiated cell. The new functions require cellular resources that compete with, and finally titrate out the resources required for proliferation, and allow an accumulation of negative regulators of the cell cycle (e.g., p27<sup>Kip1</sup>), which eventually predominate over the positive regulators. Thus, there is a reciprocal relationship between cellular differentiation and cell cycle progression/proliferation [305], though there is also evidence that differentiation and cycle arrest need not be strictly coupled [31,306,307].

Cell cycle changes in differentiating cells need not take place immediately - in some cells there is at first a boost of proliferation - as in normal hematopoiesis, or in HL60 [183,307] and U937 [153] cells differentiating in response to VDDs. In at least some of these cells, the initial burst of proliferation following the introduction

**FIGURE 86.3** The general concept of the cell cycle, and examples of factors that control cell cycle traverse and DNA replication. In most cells, the principal locus for terminal differentiation is in G0 phase, but it can also occur in G2, associated with polyploidy. In early G1, the level of phosphorylated retinoblastoma protein (P-pRB) is lower ( $<$ ) than the level of hypophosphorylated pRB protein complexed with transcription factors of the E2F family (pRB/E2F). Phosphorylation of pRB by CDK4/6-CYC D and later by CDK2-CYC E results in high levels of P-pRB, dissociation of P-pRB from the E2Fs, and transcription of E2F-regulated genes, allowing passage through the restriction point (fx1). Replication origins are bound by licensing factors in late M/early G1, creating replication-competent origins for use in S phase. Additional details of the controls of cell cycle progression are provided in the text and illustrated in Fig. 86.4. RC, replicative complex; ORC, origin recognition complex; MCM, minichromosome maintenance complex; licensing factors, ORC, MCM, and other components of the pre-RC complex; CYC, cyclin.

of the differentiating agent is not only concomitant with the initiation of differentiation, but it is required - if proliferation in those cells is inhibited when the differentiating agent is added, the differentiation process is halted [299,305]. However, even in these cases, there is an eventual slowdown of the cell cycle traverse and cessation of proliferation of differentiated cells. Consequently, numerous attempts are being made to exploit the differentiating actions of  $1,25(\text{OH})_2\text{D}_3$  and its analogs to induce proliferative quiescence of neoplastic cells, and thus increase the range of options for optimal therapy of human cancer [308].

## 4.2 Regulation of cell cycle progression

### 4.2.1 Progression through G1 and G1/S boundary

The primary drivers of G1 cell cycle transit are the kinase activities of cyclin/CDK complexes, which are controlled by a number of different mechanisms. The kinase activities of these complexes are tightly regulated by multiple mechanisms, including cyclin binding to CDKs, cyclin synthesis, cyclin degradation, cyclin/CDK phosphorylation and dephosphorylation at several key sites, and interactions with several classes of CDK inhibitors. CDKs are present throughout the cell cycle but are active only in complexes with the appropriate cyclin; each class of cyclins is synthesized and degraded

at different and specific points in the cell cycle. Mitogenic signals that stimulate cell progress through G1 increase the expression of cyclin D isoforms in early G1, which form complexes with CDK4 and/or CDK6. Later in G1, cyclin E is synthesized, peaking at the late G1/S phase boundary. The expression of cyclin E is mitogen independent, and cyclin E forms an active complex with CDK2 (Fig. 86.3). The activity of cyclin-CDK complexes depends on both activating and inhibitory phosphorylations. CDK1 and CDK2 are activated by CAK-mediated phosphorylation of Thr160/161 and inhibited by phosphorylation of Thr14 and Tyr15 by WEE1 and MIK1. Removal of Thr14 and Tyr15 phosphate groups by the CDC25A, B, and C phosphatases activates the cyclin/CDK complex. These protein phosphatases are linked to cell cycle checkpoint mechanisms, as the checkpoint kinases CHK1 and CHK2 can both phosphorylate CDC25A and target it for destruction [309–311].

Another level of CDKs regulation is provided by the CDK inhibitory proteins (CKIs), which prevent CDK activation by binding to the kinases and thus preventing their activation by cyclins. There are two major CKI families. One is the INK4 family, which includes CDKN2A (p16-INK4A), CDKN2B (p15-INK4B), CDKN2C (p18-INK4C), and CDKN2D (p19-INK4D) [312–314]. The other is the Cip/Kip family, whose main members are CDKN1A ( $p21^{Cip1}$ ) and CDKN1B

(p27<sup>Kip1</sup>). The INK4 proteins specifically block cyclin D-CDK4/6 activity leading to a G1 phase arrest, both by preventing the binding of cyclin D and by inhibition of formed CDK4/6-cyclin D complexes [315,316]. The Cip/Kip proteins are elevated during periods of both proliferation and growth inhibition [317,318] and are upregulated in a time-dependent manner after exposure of cells to differentiating agents, such as U937 cells exposed to 1,25(OH)<sub>2</sub>D<sub>3</sub> [152]. The Cip/Kip family members p21<sup>Cip1</sup>, p27<sup>Kip1</sup>, and p57<sup>Kip2</sup> are well-established inhibitors of cyclin D-CDK4/6 and cyclin E-CDK2 activities and exert significant control over the entry into the S phase [317] (Fig. 86.3). All three of these inhibitors block progression through the G1 phase but are usually activated by different stimuli. The expression of p21<sup>Cip1</sup> can be under the transcriptional control of the p53 tumor suppressor gene, activated by DNA damage [319], but may also be independent of p53 [320,321], including regulation by microRNAs [322], or 1,25(OH)<sub>2</sub>D<sub>3</sub>-activated VDR [152]. p27<sup>Kip1</sup> participates in G1 arrest produced by external stimuli such as cell–cell contact or differentiating agents as discussed in the following. While there

is a large body of evidence showing the regulation of Cip/Kip CDKIs by 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs (see the following), the control of INK4 proteins by VDDs has not been established.

The principal target of cyclin/CDK activity is the tumor suppressor pRB (Figs. 86.3 and 86.4). The phosphorylation of pRB, and other pRB-like “pocket” proteins (p130/RB2, p107) control the entry into the S phase by interacting with a member of the E2F transcription factors family. In its simplest form, the current hypothesis is that hypophosphorylated pRB binds to E2Fs and blocks their transcriptional activity; upon increased level of phosphorylation, pRB dissociates from E2F, allowing the transcription of genes necessary for S phase initiation, such as c-MYC/MAX. However, the actual situation appears to be more complicated since gene repression by pRB also involves modulation of chromatin architecture by epigenetic mechanisms [323].

#### 4.2.2 Control of S phase and DNA replication licensing

DNA replication occurs in S phase, and the basic machinery for this process is well conserved from

**FIGURE 86.4** Control of G1 to S phase transition and G1/S arrest by the pRB-E2F pathway: Regulation of Cip/Kip family CDKIs by VDDs. Phosphorylation of pRB by active CDKs releases E2F transcription factors, which activate, directly or indirectly, genes whose products are required for DNA replication [663,664]. The activity of CDKs can be controlled by multiple mechanisms including transcriptional regulation, cyclin binding, activating and inhibitory phosphorylations, and CDK inhibitor (CDKI) binding. CDKIs belong to two major families, the Cip/Kip family and the INK4 family. VDDs upregulate both p21<sup>Cip1</sup> and p27<sup>Kip1</sup> in temporally distinct patterns, which inhibit CDK/cyclin activities and G1 transit. c-MYC is one of the key genes controlled by E2Fs that regulates over 1600 known target genes.

yeast to mammals (reviewed in Ref. [324]). Replication in mammalian cells is initiated on many sites on chromosomes, designated as “replication origins,” which can exist in two states. In G1 phase, a multiprotein complex, the prereplicative complex (pre-RC), is assembled, at which time the origin is considered to be “licensed” and the chromatin becomes competent for DNA replication. Components of the pre-RC, the “initiator” proteins, include the origin recognition complex (ORC), CDC6/18, CDT1, geminin, and minichromosome maintenance 2–7 (MCM 2–7) proteins. The six MCM proteins form a hexameric complex, which may function as a replicative helicase. Once DNA replication is initiated, the complex has fewer components of the postreplicative complex (post-RC) and persists to the end of mitosis, functioning along with other molecular mechanisms, to block rereplication of DNA. At that time point, proteolytic activity destroys the cyclins and other nuclear proteins, and CDK activity becomes low. These two states of replication origins, separated by CDK activity, generally ensure that the S phase and mitosis alternate. Licensing in G1 phase is permitted after the end of mitosis, when geminin is destroyed by the anaphase promoting complex (APC)–ubiquitin system [325]. The key steps in this sequence are illustrated in Fig. 86.3.

In the higher multicellular eukaryotes but not in yeast, chromatin–ORC interactions are dynamic with ORC subunits cycling on and off replication initiation sites, which allows the changes in initiation site location that occur during differentiation [326]. When the cells exit mitosis, CDC6/18 and CDT1 are loaded on chromatin, and in turn aid loading of MCM on the pre-RC complex, thus completing licensing. The licensed complex can now be activated for DNA replication by a protein kinase, such as cyclin E/CDK2 or DBF4-dependent kinase, and the DNA replicating machinery (e.g., CDC45, replication protein A, DNA polymerase  $\alpha$  and  $\epsilon$ ) is recruited to the initiation sites.

Sites of replication in mammalian cells also change with the alterations of chromosomal architecture caused by modulation of gene activity that occurs during differentiation. Replication origin sites correlate with sites of transcriptional units, the sites of ORC1-binding correlate with transcriptional start sites, and transcription at those sites correlates with replication timing [327]. A number of pre-RC proteins are known to associate with transcription factors, including most of those implicated in stem cell maintenance and development (including c-MYC, OCT4, SOX2, Nanog, and HOXD-13), suggesting that at least part of stem cell programming and development involves the regulation of the positioning and activity of replication origins in chromatin [328].

#### 4.2.3 The G2 and M phase transition

In the G2 and M phases, cells synthesize mitotic components and segregate the duplicated DNA into equivalent, or nearly equivalent, daughter cells (reviewed in Ref. [329]). The central regulator of G2/M passage is the cyclin B–CDK1 complex. The activity of this complex is governed by factors similar to those responsible for the G1/S transition, including phosphorylation by CAK and dephosphorylation by CDC25A, CDC25B, and CDC25C. The correct segregation of duplicated chromatin into the two daughter cells requires two additional levels of regulation of proteins that bind together the two chromatids, and control of centrosome duplication and spindle assembly.

The sister chromatids adhere to one another by the adhesive properties of a multisubunit complex called “cohesin” [330]. Cohesin is dissolved by proteolytic cleavage of one of its subunits, SCC1/MED1, by separase, a calcium-activated cysteine protease [331]. The dissolution of cohesion between the chromatids occurs in two steps, one at prophase, the other at anaphase, and only the latter requires separase. Separase is regulated by cyclin B-CDK1 phosphorylation and by the inhibitor securing. Both cyclin B and securin are ubiquitinated by the APC and destroyed at the end of mitosis, thus ensuring orderly and precisely timed separation of the chromosomes at telophase [332]. Polo-like kinase-1 (PLK1) also regulates chromosome adhesion and other aspects of mitosis, including centrosome maturation and orientation. PLK1 has been reported to phosphorylate cyclin B1 and target it to the nucleus during prophase, and the finding of colocalization of PLK1 and CHK2 suggests that there is a lateral communication between the mitotic checkpoint and the DNA integrity [333,334]. Moreover, a molecular reciprocal activation between PLK1 and N-MYC was reported, which leads, among other factors, to the reduced degradation of N-MYC, cyclin E, and Mcl1 and reinforces MYC-regulated oncogenic programs [335]. Recently, it was also reported that in NSCLC cells, the transcription factor C/EBP $\beta$  directly represses Wee1 expression, which is required for the G2/M phase progression [336].

#### 4.3 Modulation of cell cycle events by vitamin D and its analogs

The changes in cell cycle traverse and DNA replication that occur in numerous forms of differentiation have been previously reviewed [305]. Changes that specifically follow exposure to VDDs have been less extensively studied, and these will now be described. The inhibition of cell cycle traverse by 1,25(OH) $_2$ D $_3$  and other VDDs has been investigated in normal and

malignant keratinocytes [337,338], and in many other types of tumor cells [339–341], with myeloid leukemia cells providing an excellent in vitro model system for this purpose [140,342,343]. Leukemic cells show complex and time-dependent responses to  $1,25(\text{OH})_2\text{D}_3$ ; for example, myeloid leukemia cell lines cultured with  $1,25(\text{OH})_2\text{D}_3$  undergo an initial proliferative burst, which is followed by growth inhibition, terminal differentiation, and subsequent apoptosis [153,344]. In U937 myelomonoblastic leukemia cells, levels of cyclin A1, D1, and E increase within 24 h of  $1,25(\text{OH})_2\text{D}_3$  treatment and then expression decreases after 48 h, a change in expression that parallels the change in cell proliferation following  $1,25(\text{OH})_2\text{D}_3$  treatment [153].

#### 4.3.1 The G1/S block

$1,25(\text{OH})_2\text{D}_3$  and its analogs inhibit proliferation of diverse types of mammalian cells by arresting them in the G1/G0 phase of the cell cycle. While the exact sequence of events from VDR activation to G1/G0 arrest remains to be elucidated and may not be exactly the same in all cell types, several pathways and cell cycle arrest effectors are already known to be involved. These include the upregulation of protein levels of the CDK inhibitors  $p21^{\text{Cip1}}$  and/or  $p27^{\text{Kip1}}$ , the upregulation of RB gene expression and phosphorylation of the pRB protein, and the inhibition of c-MYC expression [37,280,345–348].

#### 4.3.2 Upregulation of $p21^{\text{Cip1}}$ and $p27^{\text{Kip1}}$

Elevated protein levels of the Cip/Kip family of CDKIs result from the exposure to VDDs in many cell types including hematopoietic cells (Table 86.3) and may be a near-universal feature of the antiproliferative effects of these compounds. In view of the importance of CDK activity as the driving force for cell cycle progression, it is not difficult to understand that increased levels of CDKIs can target CDK complexed to cyclin D, E, or A, and grind the cell cycle traverse to a halt. However, the mechanisms of the CDKI upregulation are not entirely clear, and there are subtle differences between the antiproliferative effects of  $p21^{\text{Cip1}}$  and  $p27^{\text{Kip1}}$ . In contrast,  $p57^{\text{Kip2}}$  was seldom found to have a role in the antiproliferative effects of vitamin D and its analogs, apart from the possible involvement in the transit of osteoblasts from proliferation to differentiation [349].

In U937 myelomonocytic leukemia cells, a correlation was reported between early induction of  $p21^{\text{Cip1}}$  and the beginning of the differentiation program. The upregulation of  $p21^{\text{Cip1}}$  mRNA occurred within 4 h of the exposure to  $1,25(\text{OH})_2\text{D}_3$  independent of de novo protein synthesis, suggesting a direct transcriptional activation by VDR [152]. Indeed, the  $p21^{\text{Cip1}}$  promoter contains VDREs, and induction requires the presence of VDR. Nevertheless, some data have suggested that the

marked increase of  $p21^{\text{Cip1}}$  protein expression in response to  $1,25(\text{OH})_2\text{D}_3$  may also be due to enhanced posttranscriptional stabilization of  $p21^{\text{Cip1}}$  mRNA [350]. The transcription factor p53 is a strong inducer of  $p21^{\text{Cip1}}$ , but  $1,25(\text{OH})_2\text{D}_3$  can elevate  $p21^{\text{Cip1}}$  levels independently of p53 activity [346,351–353]. In U937, levels of cyclin A1, D1, and E increase within 24 h of  $1,25(\text{OH})_2\text{D}_3$  treatment, and then expression decreases after 48 h [153]. A strong upregulation of  $p27^{\text{Kip1}}$  protein expression was evident after 72 h exposure of HL60 cells to  $1,25(\text{OH})_2\text{D}_3$ , and the levels of the protein were dependent on the concentration of this compound [346]. This upregulation was also associated with increased levels of cyclin D1 and E, coinciding with a G1 arrest. These results suggested a prominent role of  $p27^{\text{Kip1}}$  in mediating the antiproliferative activity of  $1,25(\text{OH})_2\text{D}_3$  in this cell line. However, some redundancy of cell cycle control is likely and is exemplified by a recent report that  $p27^{\text{Kip1}}$ , CDK and E2F transcriptional repression by the pRB can have interchangeable roles in cell cycle control and tumor suppression [354]. This showed that pRB can control cell cycle progression independently of E2F.

Considerable excitement was generated when  $p21^{\text{Cip1}}$  was found to be upregulated in a number of differentiation systems, including HL60 cells and squamous cell carcinomas (SCCs) treated with  $1,25(\text{OH})_2\text{D}_3$  [320,355] (see also Fig. 86.4 and Table 86.3). It was suggested that  $p21^{\text{Cip1}}$ , and/or  $p27^{\text{Kip1}}$ , not only promote the G1 arrest but also contribute to differentiation [356]. It appears, however, that while these CDKIs may not be solely responsible for the G1 block, the data regarding their role in differentiation are conflicting. For instance, mice lacking  $p21^{\text{Cip1}}$  undergo normal development [357], even though  $p21^{\text{Cip1-/-}}$  embryonic fibroblasts show impaired arrest in G1 in response to DNA damage. An imbalance between growth and differentiation can be demonstrated in these cells, and in other in vitro cell differentiation systems with  $p21^{\text{Cip1}}$  knockouts. Keratinocytes, which are  $p21^{\text{Cip1-/-}}$ , and to a lesser extent those with  $p27^{\text{Kip1}}$  knockouts, have an increased proliferative potential [358]. With regard to differentiation, however, Harvat et al. [359] showed that growth arrest resulting from overexpression of  $p21^{\text{Cip1}}$  in mouse primary keratinocytes is not sufficient to induce the expression of markers of differentiation. Further, in malignant counterparts of these cells, the SCC cells, not even growth arrest, are clearly linked to  $p21^{\text{Cip1}}$ , as  $1,25(\text{OH})_2\text{D}_3$  inhibited growth but reduced  $p21^{\text{Cip1}}$  levels in vitro and in SCC tumors [360].

In another system, the myelomonocytic cell line U937, Freedman's group noted transcriptional activation of the  $p21^{\text{Cip1}}$  gene by  $1,25(\text{OH})_2\text{D}_3$  and suggested that this is

linked to differentiation of these leukemia cells [152]. Importantly, they identified a functional VDRE in the promoter of the p21<sup>Cip1</sup> gene and noted that the p21<sup>Cip1</sup> transcript can be detected as early as 2 h after 1,25(OH)<sub>2</sub>D<sub>3</sub> addition, consistent with p21<sup>Cip1</sup> being a direct mediator of 1,25(OH)<sub>2</sub>D<sub>3</sub> action. However, in this system, the upregulation of p21<sup>Cip1</sup> after exposure to 1,25(OH)<sub>2</sub>D<sub>3</sub> is relatively transient and accompanied by a proliferative burst [153], which does not correlate with the onset of the G1 block that is observed 24–48 h later and is accompanied by markedly increased levels of p27<sup>Kip1</sup> [152,346,347]. Thus, although

p21<sup>Cip1</sup> may initiate a cascade of unknown events that lead to the expression of the differentiated monocytic phenotype, it is unlikely to be directly responsible for the G1 arrest in leukemia, or SCC cells. Such function, however, has been attributed to p21<sup>Cip1</sup> in other cells, including prostate cancer [361–363], breast cancer [364,365], parathyroid cells [366], gastric cancer [339], or glioblastoma multiforme cells [367]. The finding that p21<sup>Cip1</sup> binds to the proliferating cell nuclear antigen (PCNA), the processive factor for DNA replication, suggests that this complex might play an important role in maintaining the integrity of the genome [368,369].

The first demonstration that upregulation of p27<sup>Kip1</sup> is associated with G1 arrest, which takes place following 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation, was reported by Wang et al. (Table 86.3) [346]. They showed a sustained increase in p27<sup>Kip1</sup> protein abundance that coincided with the appearance of the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced G1 block in HL60 cells and correlated with reduced kinase activity of CDK6 and CDK2 [346,347]. Further, reductions of the levels of p27<sup>Kip1</sup> by several independent approaches reversed the G1 block, but not the differentiated phenotype [342]. Accordingly, these data clearly show that, at least in HL60 cells, p27<sup>Kip1</sup> controls the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced G1 block, but not the differentiated phenotype.

Similar findings have been obtained in several other hematopoietic cell types, although the data cannot always be so clearly interpreted. For instance, the upregulation of p27<sup>Kip1</sup> is often accompanied by an upregulation of p21<sup>Cip1</sup> [364,370,371]. However, even in situations where p21<sup>Cip1</sup> and p27<sup>Kip1</sup> are both upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> or its analogs, increased levels of p27<sup>Kip1</sup> correlate better with the onset of G1 block than the upregulation of p21<sup>Cip1</sup> (e.g., Refs. [152,346,360,372,373]). This, however, is subject to cell context, a striking example being a report that p27<sup>Kip1</sup> is essential for the antiproliferative action of 1,25(OH)<sub>2</sub>D<sub>3</sub> on primary, but not on immortalized, mouse embryonic fibroblasts [374]. The role of CDKs in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced cell cycle arrest is also difficult to assess because, when present at relatively low levels, p21<sup>Cip1</sup> and p27<sup>Kip1</sup> serve to facilitate complex formation of cyclins D with CDKs, and their transport to the nucleus [375,376], and only high levels of CDKs are inhibitory [375,377]. Thus, one possible explanation for the upregulation of p21<sup>Cip1</sup>, which may not correlate with G1 arrest, is that p21<sup>Cip1</sup> simply serves to facilitate cyclin D–CDK complex formation. More likely, however, is that elevated levels of p21<sup>Cip1</sup> inhibit cyclin E–CDK2 activity and therefore block cyclin E–CDK2 phosphorylation of p27<sup>Kip1</sup>, which then leads to degradation of p27<sup>Kip1</sup> in proliferating cells [378–380].

Unlike p21<sup>Cip1</sup>, which can be directly upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> through a VDRE in p21<sup>Cip1</sup> promoter [152], p27<sup>Kip1</sup> has no VDR-binding element in its promoter and may be regulated in a cell type–specific and condition-specific manner by several mechanisms, which include both transcriptional and posttranscriptional levels as discussed before and illustrated in Figs. 86.2 and 86.4. The known transcriptional regulation of p27<sup>Kip1</sup> expression includes at least two mechanisms that can be influenced by 1,25(OH)<sub>2</sub>D<sub>3</sub>, though in opposing ways. One proposal is that transcription factors SP1 and NF-Y can synergistically mediate the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced expression of p27<sup>Kip1</sup> by acting directly on the p27<sup>Kip1</sup> promoter, as shown in

transiently transfected U937 leukemia cells [273]. In these experiments, deletion and mutational analysis revealed that p27<sup>Kip1</sup> promoter activation required both GGGCGG (SP1 binding) and CCAAT (NF-Y binding) sequences. Although p27<sup>Kip1</sup> promoter does not contain VDRE, Huang et al. [225] have shown that transfection of VDR in SW620 colon cancer cells, which express low level of endogenous VDR, enhances 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced p27<sup>Kip1</sup> promoter activation, and that VDR and SP1 cooperate to activate p27<sup>Kip1</sup> expression in LNCaP prostate cancer cells. Particularly, it was demonstrated that VDR physically interacts with SP1 to activate p27<sup>Kip1</sup> promoter via a GC-rich SP1 site [225]. As presented before, SP1 transcription factor is activated in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated leukemia cells; thus, these data could potentially be a plausible mechanism for the induction of G1 arrest by 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced p27<sup>Kip1</sup>, at least in myeloid leukemia cells. The second transcriptional mechanism that can be regulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> is based on the demonstration that in a number of cell types, p27<sup>Kip1</sup> is transcriptionally activated by the forkhead transcription factors, such as AFX (FOXO4) or FOXO1 [381,382], and AKT can phosphorylate and thus turn off the FOXO factors [383] allowing cell cycle progress. Interestingly, AKT can be upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [177], and thus provide an opportunity for the cells to mitigate the signals that tend to upregulate p27<sup>Kip1</sup> expression. There appear to be multiple signals for upregulation of p27<sup>Kip1</sup> expression including the AP-1 transcription factor [384], even though the precise site of its transcription origin is uncertain [385]. In addition, translational regulation of p27<sup>Kip1</sup> by the far upstream element-binding protein 1 (FBP1) binding to the unusually long 5'UTR has been reported [385].

However, as illustrated in Figs. 86.2 and 86.4, the dominant form of regulation of p27<sup>Kip1</sup> expression by 1,25(OH)<sub>2</sub>D<sub>3</sub> and other VDDs appears to be posttranscriptional, including miRNA inhibition of translation, and proteasome-dependent protein degradation. For instance, miRNAs-181 were shown to regulate the expression of p27<sup>Kip1</sup> in human myeloid leukemia cells induced to differentiate by 1,25(OH)<sub>2</sub>D<sub>3</sub> [20], as further discussed in the following. Regarding its degradation, in mouse SCC AT-84 cells, the analog EB1089 did not change p27<sup>Kip1</sup> mRNA levels, but reduced the miRNAs for p45<sup>Skp2</sup>, which ubiquitinates p27<sup>Kip1</sup>, and for CKS1, which targets p45<sup>Skp2</sup> to p27<sup>Kip1</sup> [386,387]. A similar decrease in p45<sup>Skp2</sup> expression and stabilization of p27<sup>Kip1</sup> protein was demonstrated in acute promyelocytic leukemia cells [387], ovarian cancer cells [388], and human hepatoma cells [389]. Since these changes become evident at about 48 h of the exposure to the analog, there is good correlation with the onset of the G1 block. The latent period of 24–48 h for p27<sup>Kip1</sup>

upregulation may also be needed to inactivate the cyclin E-CDK2 complex, which phosphorylates Thr187 of p27<sup>Kip1</sup> that under some conditions is required for ubiquitination of p27<sup>Kip2</sup> by p45<sup>Skp2</sup> [378]. Inhibition of cyclin E-CDK2 activity following exposure of HL60 cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> has been demonstrated [347], and this may contribute to 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced increase in p27<sup>Kip1</sup> levels. However, p27<sup>Kip1</sup> can be phosphorylated on non-CDK sites [390–392], so this form of control may have redundancy.

Another form of regulation of p27<sup>Kip1</sup> was first discovered in myeloid cells. Wang et al. found that the members of the miRNA-181 family can inhibit the expression of p27<sup>Kip1</sup>, but exposure of the cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> reduces the levels of these miRNAs and thus leads to an increase in the levels of p27<sup>Kip1</sup> and cell cycle arrest [20] (Figs. 86.2 and 86.4). As mentioned before, this role of miRNA-181a was confirmed by Cuesta et al. in myeloid cells that were treated with TPA and subsequently induced to differentiate into the macrophage differentiation phenotype [393]. Further, regulation of p27<sup>Kip1</sup> by several miRNAs was shown in other leukemic cells [394–396]. It seems that such multiple controls by 1,25(OH)<sub>2</sub>D<sub>3</sub> of p27<sup>Kip1</sup> expression signify an especially critical role of 1,25(OH)<sub>2</sub>D<sub>3</sub> in cell cycle regulation.

#### **4.3.3 Retinoblastoma protein control of 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced G1 block**

The suggested placement of the inactivation of the cyclin E-CDK2 complex upstream of p27<sup>Kip1</sup> upregulation raises the question of how this complex is inactivated in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated cells. One possible answer is provided by the finding that the RB gene is upregulated early in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation of HL60 cells [37], as illustrated in Fig. 86.4. The increased levels of pRB can then bind and inactivate E2F transcription factors necessary for the expression of cyclin E, and thus the activity of the cyclin E-CDK2 complex (Fig. 86.4). Accordingly, the phosphorylation of Thr187 on p27<sup>Kip1</sup> is reduced, allowing the accumulation of this CDKI, and a further increase in the hypophosphorylated forms of pRB, also a substrate for the cyclin E-CDK complex. Hypophosphorylated pRB now further binds E2F and thus reduces cyclin E expression to the point that p27<sup>Kip1</sup> is no longer phosphorylated and degraded, as the result of this positive feedback loop, leading to G1 arrest. It is known that in HL60 cells, the expression of pRB normally occurs primarily during G1 phase and can be detected at both mRNA and protein levels within 12 h of exposure to 1,25(OH)<sub>2</sub>D<sub>3</sub> [37,293] although the mechanism of its upregulation remains to be determined. These in vitro studies are supported by the finding of gross defects in the development of the hematopoietic system in RB-

KO mice [406,407], and by the transcriptional studies that show that the RB gene plays a role in normal human adult hematopoiesis [408]. Thus, pRB appears to have a role in the early stage of 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation, and to contribute to changes in cellular transcriptional and kinase activities that lead to G1 arrest at a later stage [409].

#### **4.3.4 Downregulation of c-MYC expression in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation and G1 arrest**

The pRB/E2F pathway also controls the expression of c-MYC, as E2F transcription factors upregulate the c-MYC gene, and inhibition of c-MYC expression by 1,25(OH)<sub>2</sub>D<sub>3</sub> may be responsible, at least in part, for the G1 block in differentiating cells (Fig. 86.4) [410]. Indeed, the association between c-MYC downregulation and 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation of human leukemia cells was one of the earliest findings that initiated the studies of the molecular basis of the cellular changes that follow exposure to this hormone [2,280,411,412]. Subsequently, several studies have shown a marked reduction in c-MYC expression in response to 1,25(OH)<sub>2</sub>D<sub>3</sub> and analog treatment of colon cancer cells [413,414] and prostate cancer cells [348,415], and this was associated with the induction of differentiation [414] and G1 arrest [415]. The intense interest in c-MYC as a potential negative regulator of differentiation was fueled largely by its deregulated expression in several types of human neoplasia [416,417]. c-MYC is known to promote cell cycle progression mostly through coordinated transcriptional regulation of target genes (e.g., Ref. [418]). These include the DNA replication and cell cycle traverse-promoting genes such as ornithine decarboxylase, CDC25A, and cyclins E and A [416]. Conversely, c-MYC inhibits the transcription of cell cycle inhibitor p21Cip1 [419], and it has been suggested that this is due, at least in part, by sequestering the SP1 transcription factor [420] or by inhibiting ERK and P70S6K/4EBP1 phosphorylation [421], which are required for p21Cip1 transcription. While the aforementioned considerations present an almost complete sequence of events that can explain the G1 arrest induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> (summarized in Fig. 86.4), an additional level of control of c-MYC expression by 1,25(OH)<sub>2</sub>D<sub>3</sub> is provided by studies of Simpson et al. [422]. They found that in differentiating HL60 cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> increased the expression and DNA-binding activity of HOXB4, a product of a homeobox gene, and that HOXB4 binds to the sites in the c-MYC gene, which are involved in blocking by 1,25(OH)<sub>2</sub>D<sub>3</sub> of the elongation of c-MYC transcripts [284]. Further, these authors demonstrated that a HOXB4 antisense oligonucleotide partially inhibited the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced decrease in c-MYC protein levels [423]. While

they observed reduction of  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation in these experiments, the effect of HOXB4 antisense on the G1 block was not reported. Nonetheless, these studies are significant, as members of the HOX gene family are known to be involved in hematopoiesis and leukemogenesis [424–426]. Also, other HOX genes participate in  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation; HOXB7 was reported to increase in HL60 cells [427], while in U937 and MCF-7 cells  $1,25(\text{OH})_2\text{D}_3$  increased expression of HOXA10 [285], and the Iroquois homeobox gene 5 (IRX5) is regulated by  $1,25(\text{OH})_2\text{D}_3$  in LNCaP human prostate cancer cells, and controls the cell cycle as well as apoptosis [428].

Available data suggest that  $1,25(\text{OH})_2\text{D}_3$  may inhibit colon cancer cell proliferation by inhibiting the APC/ $\beta$ -catenin pathway. For instance, in SW480 cells,  $1,25(\text{OH})_2\text{D}_3$  promotes VDR/ $\beta$ -catenin interaction and prevents  $\beta$ -catenin nuclear translocation, leading to inhibition of TCF-4 responsive genes such as c-MYC [55], a proto-oncogene required for formation of tumors in many settings. Thus, transcriptional blockage of c-MYC expression in these cells after exposure to  $1,25(\text{OH})_2\text{D}_3$  [413] may be associated with modulation of the APC/ $\beta$ -catenin signaling pathway. Another mechanism by which  $1,25(\text{OH})_2\text{D}_3$  can downregulate c-MYC expression was suggested by Rohan et al. [348], who demonstrated that treatment of C4-2 prostate cancer cells with  $1,25(\text{OH})_2\text{D}_3$  resulted in a 50% decrease in c-MYC mRNA but a much more extensive reduction in c-MYC protein. Further experiments showed that decreased c-MYC stability was due to an increase in the proportion of c-MYC phosphorylated on Thr58, a glycogen synthase kinase-3 $\beta$  (GSK3 $\beta$ ) site that serves as a signal for ubiquitin-mediated proteolysis. Thus, it appears that  $1,25(\text{OH})_2\text{D}_3$  regulates c-MYC levels in cancer cells by several different pathways, which involve both a reduction in c-MYC gene expression and a decrease in c-MYC protein stability.

#### 4.3.5 G2/M retardation and polyploidization

The occurrence of abnormalities in G2/M transition in  $1,25(\text{OH})_2\text{D}_3$ -treated cells has been observed infrequently, with a general consensus that the G1 phase is the principal target of the antiproliferative actions of  $1,25(\text{OH})_2\text{D}_3$  and its analogs. However, in early studies of  $1,25(\text{OH})_2\text{D}_3$  action, Abe et al. [187] detected an increase in the G2/M compartment in WEHI murine myelomonocytic cells, also described in HL60 cells by Godyn et al. [306]. The basis for this increase may be a reduction in the levels of CDK1 in these cells [429], although the roles of cohesin, separase, or PLKs remain to be investigated in the light of the recently accumulating knowledge of mitotic controls. The  $1,25(\text{OH})_2\text{D}_3$ -induced G2 arrest is also seen in LNCaP prostate cancer cells, which is due to  $1,25(\text{OH})_2\text{D}_3$ -mediated upregulation of

miRNA-98, a miRNA with tumor suppressor properties [430]. The combination of  $1,25(\text{OH})_2\text{D}_3$  and PS121912, a VDR coactivator inhibitor, arrested HL60 cells in S and G2 by downregulating E2F1 and E2F4, causing the downregulation of cyclins D and A and subsequent cell cycle arrest [431].

One consequence is the higher ploidy of HL60 cells exposed for prolonged periods of time to  $1,25(\text{OH})_2\text{D}_3$ , observed as an increased number of binucleated cells [306], or as nearly doubled DNA content of these cells [254]. Interestingly, polyploidization of  $1,25(\text{OH})_2\text{D}_3$ -treated cells is an alternative to differentiation, as these cells override the antiproliferative actions of  $1,25(\text{OH})_2\text{D}_3$  and do not express differentiated phenotype [254]. Thus, HL60 cells can have a  $1,25(\text{OH})_2\text{D}_3$ -induced defect in completion of mitosis that allows one round of DNA endoreduplication. Whether osteoclast, or perhaps megakaryocyte, polyploidization is also influenced by  $1,25(\text{OH})_2\text{D}_3$  remains a possibility.

#### 4.4 Inhibition of cell proliferation by vitamin D and analogs without evidence of differentiation: cell type specificity

While some effects of  $1,25(\text{OH})_2\text{D}_3$  and its analogs can be recognized in a variety of cell types, there is remarkable cell type specificity of most of such effects, and it is important to realize that only a few generalizations can be made regarding the antiproliferative actions of these compounds. However, it appears to be true that  $1,25(\text{OH})_2\text{D}_3$ -induced differentiation is not simply a consequence of inhibited proliferation, as differentiation often precedes the G1 block [307], and  $1,25(\text{OH})_2\text{D}_3$  can inhibit cell proliferation with only minimal, or absent, evidence of differentiation. Indeed, the antiproliferative effect of  $1,25(\text{OH})_2\text{D}_3$  on cultured melanoma cells was recognized by Colston et al. [432] in 1981, at the same time as the differentiation-inducing action of  $1,25(\text{OH})_2\text{D}_3$  was described in myeloid leukemia cells by Abe et al. [1]. A recent example of inhibition of growth without differentiation is the report that in human airway, smooth muscle cells  $1,25(\text{OH})_2\text{D}_3$  decreased PDGF-induced cell growth by inhibiting pRB and CHK1 phosphorylation [433]. Cell specificity of responses to  $1,25(\text{OH})_2\text{D}_3$  is also illustrated by the finding that  $1,25(\text{OH})_2\text{D}_3$  can cause a G1 block in cultured thyroid carcinoma and pituitary corticotroph, but not lactotroph, cells [434,435]. Interestingly, while in thyroid carcinoma cells, the mechanisms of the antiproliferative effects include dephosphorylation of p27<sup>Kip1</sup> in a PTEN-dependent manner, leading to a diminished association between p45<sup>Skp2</sup> and p27<sup>Kip1</sup> with its consequent accumulation [434], in pituitary corticotroph cells, the mechanism appears to be a diminished association of

p27<sup>Kip1</sup> with p45<sup>Skp2</sup> and CDK2, without an involvement of PTEN [435]. This illustrates not only the exquisite cell type specificity of the mechanisms involved in the antiproliferative actions of vitamin D and its analogs, but also that the upregulation of p21<sup>Kip1</sup> is unrelated to differentiation, as demonstrated previously in leukemia cells [342].

Another mechanism for the antiproliferative actions of 1,25(OH)<sub>2</sub>D<sub>3</sub> on cell types that show only minimal evidence of differentiation is provided by the apoptosis-inducing actions of vitamin D and its analogs, as described in the next section and in other chapters in this volume. Again, cell type determines this response, as in contrast to various carcinomas, e.g., breast cancer cells [436], 1,25(OH)<sub>2</sub>D<sub>3</sub> protects HL60 leukemia cells from apoptosis, as first demonstrated by Xu et al. [437] and further confirmed by subsequent studies in both HL60 cells [177,178,438,439] and other cancer [440] and noncancer [441–444] cell types. Thus, the activity of survival pathways may determine whether differentiation can take place in the presence of 1,25(OH)<sub>2</sub>D<sub>3</sub>, or whether a potential default pathway will lead to apoptosis, perhaps as the result of prolonged residence in a cell cycle compartment other than G0. In any case, 1,25(OH)<sub>2</sub>D<sub>3</sub> can be an effective antiproliferative agent in many cell types that express VDR.

## 5. Effects of VDDs on cell survival and cell death

### 5.1 VDDs can increase cell death

Depending on the cell type, VDDs can either protect the cells from death or lead to their demise. For instance, VDDs have been reported to induce apoptosis in cells derived from murine squamous cell carcinoma [445], in cell lines derived from human breast cancer cells [446], or human hepatocellular carcinoma (HCC) cells [447]. VDDs can also activate genes and proteins responsible for apoptosis of other cell types, such as colon and prostate cancer cells [448,449]. Many reports presented evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs activate the expression of proapoptotic proteins BAK and BAX and suppress the antiapoptotic BCL family members, BCL2 and BCL-xL [450,451]. This causes the efflux of cytochrome c from the mitochondria to the cytoplasm and triggers the activation of the downstream executor caspases such as caspase-3, as well as the upstream initiator protease caspase-9, and induction of apoptosis [452]. The mechanism of 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced apoptosis varies with the cell type and can be mediated by either p53-dependent, or independent pathways [453–456]. Moreover, it has been shown that 1,25(OH)<sub>2</sub>D<sub>3</sub> may induce apoptosis by dysregulation of the signaling pathways activated by different growth factors and its

receptors. For example, it downregulates insulin-like growth factor receptor (IGFR) [457] as well as upregulates tumor necrosis factor alpha (TNFα) [458].

It was also shown that either 1,25(OH)<sub>2</sub>D<sub>3</sub> or its analogs, EB1089 and ILX23-7553, can potentiate the response to ionizing irradiation [456,459–461]. For the analog EB1089, such activity was detected in MCF-7 breast tumor xenografts in nude mice [462]. In these studies, the effect of EB1089 combined with radiation on growth of human breast cancer xenografts was greater than radiation alone, raising the possibility that EB1089 interfered with DNA repair. It seems that cell death induced by irradiation in the presence of EB1089 is a consequence of alterations in signaling pathways downstream of the DNA damage. These signaling pathways may also involve the generation of reactive oxygen species, acceleration of cell senescence, and c-MYC independent apoptosis, as well as p53-dependent cell death by autophagy [461].

### 5.2 VDDs can increase cell survival

In contrast to studies described before, AML cells are protected from death by VDDs [439]. Other examples include fibroblasts, keratinocytes, and primary melanocytes, in which 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation is accompanied by increased cell survival and decreased apoptosis [177,178,439,463]. In melanocytes, sphingosine 1-phosphate was identified as a downstream mediator of 1,25(OH)<sub>2</sub>D<sub>3</sub> actions [463]. Interestingly, in mice, 1,25(OH)<sub>2</sub>D<sub>3</sub> administration prevented bleomycin-inducing lung interstitial tissue damage that leads to lung fibrosis [464].

The older literature also showed that 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation of AML cells can be divided into several phases. During the initial phase, the cells proliferate normally, and cell cycle progression is driven by the high levels of MEK1/2, ERK1/2, and JNKs [183,184,251]. At the later phase, c-RAF protein activates ribosomal S6 kinase p90RSK that together with other kinases, such as ERK1/2 and ERK5, activates the master transcription factor for monocytes/macrophages differentiation, C/EBPβ [33,192,294]. Prosurvival signals transmitted from RAF1 to downstream targets are augmented by KSR1 and KSR2, essential for RAF1 activation and/or phosphorylation [154,155,465–467]. KSR2 knockdown decreases cell survival, which is accompanied by reduced BCL2/BAX and BCL2/BAD ratios and increased cleavage of caspase-3 [439]. Moreover, during the later phase of 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation of AML cells, elevated expression of other antiapoptotic proteins, BCL-xL and MCL1, facilitates differentiation by increasing cell survival [178]. Additionally, in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiating AML cells,

expression of proapoptotic protein BIM is inhibited by miRNA-32 [468].

In the more recent literature, it seems to be a general finding that in cells with DNA damage, exposure to VDDs enhances cell death [469,470]. This was examined in detail in AML cells treated by AraC, the standard chemotherapeutic agent for this disease, and remarkably, the enhancement of cell death was selective for malignant blasts, as the AraC-induced cell death of normal bone marrow cells was not increased by VDDs [471,472]. In these experiments, the effect was potentiated by combination of a vitamin D<sub>2</sub> derivative, doxercalciferol (Dox) with a botanical, carnosic acid (CA) [471,472]. It is likely that the survival enhancing action of the combination (Dox/CA) is primarily due to the increased expression of VDR in the presence of CA, as a previous publication demonstrated that CA markedly increases the levels of VDR protein [473]. The requirement for VDR to obtain an optimal cell death-enhancing effect was also shown by siVDR transfection of AML cells [472]. The initial studies of the molecular mechanisms demonstrated that the enhancement of cell death by the differentiation-inducing combination Dox/CA was executed largely by caspase-3, activated downstream from the proapoptotic SH3-only protein BIM, most likely via caspase-9 [472]. It was speculated that the choice between DNA repair and apoptosis can be determined by the Tyr-142 phosphorylation of the DNA damage-related protein H2AX [474]. In this scenario, the DNA repair–apoptosis switch depends on several factors, including the binding of JNK stress-related protein kinase to H2AX phosphorylated on Tyr-142. This then leads to apoptosis in the system studied. The role of VDDs in this experimental system remains to be investigated, but since VDDs upregulated JNK expression in AML cells [259,475,476]. Recent studies in AML cells revealed that direct activation of ASK1 kinase by thioredoxin-interacting protein (TXNIP) is required for the optimal transmission of the cell death signal to apoptotic machinery and is regulated by JNK and BIM [477]. This is an interesting possibility for VDDs-based clinical applications.

### 5.3 Autophagy and VDDs

In addition to its effects on apoptosis, 1,25(OH)<sub>2</sub>D<sub>3</sub> can regulate the induction of autophagy, which affects cell survival, although the details vary significantly depending on the type of cell and cellular stress. In some circumstances, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits the cytoprotective effects of autophagy and facilitates cell death, which can be advantageous in the design of cancer chemotherapy regimens. In breast and non–small-cell lung cancer cell lines exposed to radiation, both

1,25(OH)<sub>2</sub>D<sub>3</sub> and its analog EB1089 promote a prolonged cell cycle arrest, inhibit the normal proliferation-related recovery from radiation damage, and reduce the normal cytoprotective effects of autophagy, thus enhancing the effectiveness of radiation treatment against these tumor cells [478].

However, in most cells studied, 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates autophagy and promotes cell survival. In cardiomyocytes, 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated VDR activation protected against ischemia/reperfusion injury by promoting autophagy, mediated in part by supporting the enhanced activation of Beclin-1 [479]. In human monocytes and macrophages, 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates expression of the ASAP2 gene, which encodes a multi-domain protein that localizes in the Golgi and plasma membrane and is involved in vesicle transport and autophagy [480]. In endothelial cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> may prevent cell death by reducing the expression of apoptosis-inducing proteins and upregulating the expression of Beclin-1, thus enhancing autophagy and downregulating apoptosis [481]. Most relevant to this chapter, in macrophages, 1,25(OH)<sub>2</sub>D<sub>3</sub> and a functional VDR are critical in activating autophagy and autophagic defenses against mycobacteria infection [482]. Normal macrophages demonstrate significant release of TNF $\alpha$ , I- $\kappa$ B degradation, and NF- $\kappa$ B nuclear translocation in response to *Mycobacterium tuberculosis* infection. This response is greatly reduced in HIV-infected macrophages, whereas 1,25(OH)<sub>2</sub>D<sub>3</sub> pretreatment restores TNF $\alpha$  release and NF- $\kappa$ B nuclear translocation [483]. 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated autophagy may also play a role in slowing HIV infection. For instance, in macrophages, TLR8 ligands activate a 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated autophagic response that inhibits HIV-1 infection [484]. Also, it has been reported that an intraperitoneal injection of 25(OH)D<sub>3</sub> protects mouse skin from UV damage. This effect is mediated chiefly by antiinflammatory M2 macrophages [485].

In another system, 1,25(OH)<sub>2</sub>D<sub>3</sub> was found to trigger an “autophagic switch” and reprogram ZR-75-1 breast cancer cells from radiation alone–induced cytoprotective autophagy to cytotoxic autophagy when treated with radiation plus 1,25(OH)<sub>2</sub>D<sub>3</sub> [486,487]. This interesting concept may encourage similar studies in hematopoietic cells, e.g., in reference to health disparities, as autophagy regulation by 1,25(OH)<sub>2</sub>D<sub>3</sub> in primary monocytes–macrophages appears to be varying between black and white individuals [488].

## 6. Effects of VDDs on lymphoid lineage cells and immunity

While the bulk of studies of the effects of VDDs and their therapeutic potential in hematologic malignancies

focus on the myeloid lineage hematopoietic cells, lymphoid cells can also recognize the presence of VDDs and respond in various ways.

### 6.1 Immunoregulatory actions of VDDs on hematological malignancies: reversing the leukemia-induced immunodeficiency

All immune cells are progeny of the hematopoietic stem cells (HSCs), which, when driven by intrinsic and extrinsic signals in the bone marrow, undergo differentiation steps to produce various types of blood and immune cells [489].

The character of the immune dysfunction in hematological malignancies depends on the type of the disease. For instance, in myeloid leukemias, the dysfunction affects innate, while in lymphoid leukemias an acquired immune system, due to the replacement of immune cells by cancer cells. Thus, all leukemias, and especially acute types, are accompanied by an increased risk of infections [490].

The primary goal in the treatment of leukemias is an elimination of rapidly proliferating leukemic blasts. However, chemo- or radiotherapy not only removes proliferating blasts but also prevents the remaining immune cells from being activated, since immune activation is always accompanied by a proliferation. One of the most common, and most dangerous consequences, of chemotherapy is neutropenia, which results in severe fungal infections [491]. In this way, chemotherapy-induced immunodeficiency adds to the leukemia-induced immunodeficiency.

The need to improve functions of the immune system has been appreciated predominantly in patients with chronic lymphocytic leukemia, the disease in which lenalidomide appeared to have two activities, antitumor and immunostimulatory [492]. The idea to apply other compounds, which stimulate development and function of immune cells, is rational. One class of such compounds is  $1,25(\text{OH})_2\text{D}_3$  and low-calcemic VDDs.

#### 6.1.1 $1,25(\text{OH})_2\text{D}_3$ and hematopoiesis

The presence of  $1,25(\text{OH})_2\text{D}_3$  seems not to be essential for human hematopoiesis, since as mentioned before, VDR-KO mice have normal numbers of all types of blood cells, but these mice are not able to respond properly to pathogens [12]. When exposed to pathogens, the mice without VDR respond with production of chronic myeloid leukemia-like cells, splenomegaly, granulocytosis, thrombocytosis, and reduced erythropoiesis [493]. However, both murine and human HSCs express VDR, and the receptor is transcriptionally active in these cells [291]. The physiological level of  $1,25(\text{OH})_2\text{D}_3$  is

necessary to keep HSCs in a proliferating state [15] and to induce monocytic markers of differentiation [13]. The aforementioned facts prompted investigation of supporting hematopoiesis after autologous stem cell transplantation (HSCT) using  $1,25(\text{OH})_2\text{D}_3$ . The results of the randomized study performed on 80 patients after HSCT revealed that  $1,25(\text{OH})_2\text{D}_3$  improved lymphocytes recovery and a 2-year relapse-free survival in patients, without producing adverse side effects [494]. Not only did  $1,25(\text{OH})_2\text{D}_3$  improve patient recovery after HSCT, but it also reduced a risk of graft versus host disease (GVHD) [495,496].

#### 6.1.2 $1,25(\text{OH})_2\text{D}_3$ and innate immunity

The capability of  $1,25(\text{OH})_2\text{D}_3$  to regulate human immune system has been known for many years. However, the ability to perform genome-wide analyses have provided deeper insight to understanding this process [497]. These studies performed in cancer cell lines have revealed that among hundreds of VDR-regulated genes, many belong to the immune system [47,498]. Many of these immune-related genes were upregulated by  $1,25(\text{OH})_2\text{D}_3$  in blood cells of healthy people, as well [47,499]. The cells that appear to be the most important targets of  $1,25(\text{OH})_2\text{D}_3$  in the immune system are macrophages and dendritic cells. These cells not only have high expression of VDR [32] but are also able to produce  $1,25(\text{OH})_2\text{D}_3$  from its precursor  $25(\text{OH})\text{D}_3$  [500]. Furthermore,  $1,25(\text{OH})_2\text{D}_3$  is capable of directly regulating the expression of genes responsible for monocyte/macrophage functions, such as CD14 [501,502], cathelicidin [503], or  $\text{TNF}\alpha$  [504]. This ability supports the immune defense against *M. tuberculosis* [503], dengue virus [505], HIV [506], or cancer [507]. However, the influence of  $1,25(\text{OH})_2\text{D}_3$  toward human innate immune response is more complex than just the upregulation of the immune-related genes. It has been shown that pretreatment of human monocytes with  $1,25(\text{OH})_2\text{D}_3$  reduces their production of IL-6 and  $\text{TNF}\alpha$  in response to bacterial lipopolysaccharide (LPS) [508]. There are also reports that suggest that the physiological levels of vitamin D may prevent damage in the human body caused by a “cytokine storm” in response to viral infections [509]. Indeed, several groups have reported that the incidence and the severity of COVID-19 infections correlate with vitamin D insufficiency [510–514].

#### 6.1.3 $1,25(\text{OH})_2\text{D}_3$ and acquired immunity

As indicated before, murine T and B lymphocytes express the VDR gene, however, at a lower level than HSCs and thymocytes [515]. Nevertheless, many studies have revealed that in mice and in humans, all cell types of the acquired immune system respond to  $1,25(\text{OH})_2\text{D}_3$ .

### 6.1.3.1 T lymphocytes

Subsets of T lymphocytes (T cells), including both resting T cells (expressing either CD8 or CD4) and activated T cells, express VDR [129,516,517]. VDR mRNA expression increases when these cells are stimulated to proliferate, for example, after their exposure to the mitogen phytohemagglutinin-A (PHA) for 24 h *in vitro*. VDR mRNA was detected by RT-PCR in murine intraepithelial lymphocytes and regulatory T cells (Treg) expressing FoxP3, CD4, and CD25 [517,518].

Several studies of VDR-KO mice provided insights into the role of VDR in lymphoid cells [12,519]. Although the proportions of T and B cells are normal in the VDR-KO mice, antigen-stimulated spleen cells from VDR-KO mice produce less interferon ( $\text{IFN}\gamma$ ) and more IL-4 than those from WT mice, indicating impaired Th1 differentiation. Additionally, IL-12 stimulation induces a weaker proliferative response in VDR-KO splenocytes than those in WT mice, and expression of STAT4 is reduced. These results suggested that VDR plays an important role in the Th1-type immune response, but not in thymocyte development.

Tregs are phenotypically, functionally, and quantitatively normal in VDR-KO mice. However, the number of intraepithelial lymphocytes is reduced in VDR-KO mice, resulting in the failure of T cell homing into the gastrointestinal tract, and this possibly increases a risk of developing inflammatory bowel disease [518]. Tregs, an important cell subset of T cells, respond to  $1,25(\text{OH})_2\text{D}_3$  by a shift in their polarization, increasing percentages of Th2 and Treg cells, and decreasing percentages of Th1 and Th17 cells in peripheral blood of rodents [520,521]. This mechanism is most likely responsible for the beneficial effects of  $1,25(\text{OH})_2\text{D}_3$  that have been observed in patients with Th1-mediated autoimmune diseases, such as type 1 diabetes mellitus [522], multiple sclerosis [523], or psoriasis [524]. The precise mechanism of T cell polarization in response to  $1,25(\text{OH})_2\text{D}_3$  has not been fully elucidated, but  $1,25(\text{OH})_2\text{D}_3$ -induced increases in the expression of FOXP3, IL-10, and TGF- $\beta$ 1 in T cells were observed [525].

A report on VDR-KO mice showed that pathogen-specific effector and memory CD8 T cells respond differently to intracellular viral and bacterial pathogens in the presence or absence of  $1,25(\text{OH})_2\text{D}_3$  signals. However, the  $1,25(\text{OH})_2\text{D}_3$  signals serve to regulate antigen-specific effector and memory CD8 T cell size, repertoire, and survival. One mechanism by which  $1,25(\text{OH})_2\text{D}_3$  mediates the T cell repertoire is the inhibition of CYP11A1 transcription by  $1,25(\text{OH})_2\text{D}_3$ -bound VDR via interactions with the CYP11A1 promoter [526]. CYP11A1 facilitates the IL-4-mediated conversion of  $\text{IFN-}\gamma$  secreting CD8+ T cells (Tc1) to IL-13 secreting CD8+ T cells (Tc2); the former more involved in

antitumor activity, and the latter more involved in allergic and asthmatic responses. The use of VDR-KO mice also showed that there are potential regulatory connections between VDDs and effector as well as memory CD8 T cell differentiation events during infections [527]. The absence of  $1,25(\text{OH})_2\text{D}_3$  signals leads to aberrant CD8 T cell effector differentiation, enhanced contraction in antigen-specific cytotoxic T lymphocytes (CTLs), a significantly restricted breadth of the antigen-specific CD8 T cell effector and memory repertoire, and preferential localization of effector and memory CD8 T cells to the lymph nodes compared with nonlymphoid tissues [519,527]. The implications of the aforementioned findings for malignant disease may relate to the functional state of host defenses against aberrant cells due to their neoplastic transformation.

### 6.1.3.2 B lymphocytes

B lymphocytes are also regulated in response to  $1,25(\text{OH})_2\text{D}_3$ . In humans,  $1,25(\text{OH})_2\text{D}_3$  has been shown to inhibit proliferation and enhance apoptosis of activated B cells and to inhibit production of immunoglobulins (Ig) by plasma cells [528]. The influence of  $1,25(\text{OH})_2\text{D}_3$  is most probably mediated by IL-10, the cytokine that inhibits B cells migration, induces class switch from IgE to IgM [529]. IgG and IgA also block activation of cytotoxic T cells [529].

The regulation of VDR expression in B cells is principally at the transcriptional level [129,516]. No VDR mRNA or protein is detected in resting B lymphocytes, for example, in normal human B cells from tonsils, until their activation [516,530]. *In vitro*  $1,25(\text{OH})_2\text{D}_3$  inhibits the synthesis of Ig by plasma cells [402,528]. Their inhibition may be mediated through the activation of VDR/RXR in these cells, and/or through the inhibition of Th helper cell activity [531]. Production of lymphokines, including IL-2, is markedly decreased by  $1,25(\text{OH})_2\text{D}_3$  in activated T lymphocytes, and this could cause the suppression of Ig synthesis [532–534].

Non-Hodgkin's lymphoma and Burkitt's lymphoma B cell lines have been shown to express only low levels of VDR; yet  $1,25(\text{OH})_2\text{D}_3$  ( $10^{-7}$  M) can decrease the proliferation of these cells *in vitro* [535]. More recently, it has been observed that low levels ( $<20$  ng/mL) of serum  $25(\text{OH})\text{D}_3$  are associated with reduced survival of patients with follicular lymphoma [536]. Clearly, further investigations are needed to determine the effects of vitamin D supplementation in this clinical setting.

The immunomodulatory actions of  $1,25(\text{OH})_2\text{D}_3$  can influence not only diseases of the immune system but also neoplasms. The devastating role of cancer-associated inflammation, which creates an indispensable and important environment for the growth of

neoplasms, has been very well documented [537]. Cancer cells secrete various cytokines and growth factors, which attract immune cells to the tumor site, support its development, and create an environment where angiogenesis and lymphangiogenesis are promoted [538]. Inhibition of the devastating inflammation by  $1,25(\text{OH})_2\text{D}_3$  and its low-calcemic analogs, accompanied by an enhanced degradation of pathogens, suggests that these compounds can be promising agents to support anticancer treatment.

## 7. Clinical applications of VDD actions against hematopoietic malignancies

### 7.1 Differentiation therapy of leukemia

A typical abnormality of leukemic cells is that they harbor a block at an early stage of HSC development and fail to differentiate into functional mature cells. As discussed before, numerous early studies popularized the strategy of inducing differentiation and growth arrest as an alternative to inducing the death of cancer cells by cytotoxic therapies. The potential for differentiation therapy to improve outcomes in leukemia is exemplified by the development of therapy with ATRA for the targeted treatment of APL, also known as AML-M3. ATRA is specifically effective in APL cells carrying a typical chromosomal translocation between chromosomes 15 and 17 (t [15,17](q22;q21)), the fusion product of which is PML-RAR $\alpha$ . The leukemia with translocation NPM/RAR $\alpha$ , but not other leukemias including PLZF/RAR $\alpha$  translocation leukemia, is also responsive to treatments with ATRA, ATRA/As $_2$ O $_3$ , or ATRA together with other compounds [539].

Since  $1,25(\text{OH})_2\text{D}_3$  was first noted to induce leukemia cell differentiation [1] and extends the survival of mice inoculated with these cells [540], numerous findings obtained in various models of cancer demonstrated that  $1,25(\text{OH})_2\text{D}_3$  can be an effective anticancer agent [4,541,542]. However, the mechanistic basis for clinical trials of VDDs as potential drugs for differentiation therapy of leukemia and other malignancies is still being developed.

### 7.2 VDDs and their functional analysis

A problem with using  $1,25(\text{OH})_2\text{D}_3$  is its hypercalcemic effect, which prevents clinical use of doses effective in arresting or killing cancer cells in model systems. To overcome this problem, many analogs of  $1,25(\text{OH})_2\text{D}_3$  have been synthesized that have enhanced potency to inhibit proliferation and promote differentiation of cancer cells but have lower calcemic activity than the parent compound [541,542]. Vitamin D $_2$  (ergocalciferol) has

been shown to exhibit essentially the same general biological effects as vitamin D $_3$  (cholecalciferol), though there is some controversy regarding relative biopotencies of the two compounds in model systems and in humans [543,544]; also reviewed in Ref. [545]. A direct comparison of the two  $1,25$ -dihydroxyvitamin D derivatives,  $1,25(\text{OH})_2\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_2$ , at spectrophotometrically validated concentrations in a panel of AML cell lines representing different stages of myeloid maturation (KG-1a, HL60, U937, MOLM-13) revealed significantly lower prodifferentiation potency of  $1,25(\text{OH})_2\text{D}_2$  [546]. On the other hand, there is evidence that vitamin D $_2$  and its derivatives are less toxic than vitamin D $_3$  compounds in animals [545,547].

Studies in cell culture in vitro showed that many VDDs are between 10- and 1000-fold more active than  $1,25(\text{OH})_2\text{D}_3$  in their growth-suppressive and differentiation-inducing activity [548,549]. These VDDs can provide a larger therapeutic window for the treatment of hematologic malignancies and should be considered for the selected trials in hematologic malignancies alone, though it is far more likely to be effective in combination with other therapies.

However, it should be remembered that there are important cell type and species differences in the activities of these compounds, and many analogs are no longer available from the manufacturers. Those previously explored and some currently of promise for treatment of AML and myelodysplastic syndrome (MDS) include alfacalcidol, inecalcitol, paricalcitol, doxercalciferol, and others.

#### 7.2.1 Alfacalcidol

The first attempts to use analogs focused on  $1\alpha(\text{OH})\text{D}_3$  (alfacalcidol), a vitamin D $_3$  compound that is efficiently converted to  $1,25(\text{OH})_2\text{D}_3$  in vivo by D $_3$ -25-hydroxylase. Alfacalcidol has been widely used since 1981 as a prodrug for  $1,25(\text{OH})_2\text{D}_3$  in the treatment of hypocalcemia, chronic renal failure, hypoparathyroidism, and osteoporosis [541,550]. This compound effectively induced differentiation and inhibited proliferation of U937 monoblastic leukemia cells [551]. Alfacalcidol was administered to mice inoculated with M1 leukemia cells, and it showed greater antileukemic activity than  $1,25(\text{OH})_2\text{D}_3$  [540]. Its conversion to the active form resulted in a prolonged elevation of plasma levels of  $1,25(\text{OH})_2\text{D}_3$ , and the dosage of 25 pmol every other day, prolonged survival by 50%–60% while producing only a slight increase in the serum calcium.

#### 7.2.2 Inecalcitol

The 19-nor-14-epi-23-yne- $1,25(\text{OH})_2\text{D}_3$  analog of vitamin D $_3$  (inecalcitol) has been first described in 2000 [552] and analyzed in detail in breast cancer [552], prostate cancer [553], and SCC [554] models. In HL60 cell

cultures, inecalcitol was about 6- and 11-fold more potent than  $1,25(\text{OH})_2\text{D}_3$  in inducing cell differentiation [555] and inhibiting proliferation [553], respectively. The maximum tolerated dose was 30  $\mu\text{g}/\text{mouse}$  (i.p., every other day) compared with 0.0625  $\mu\text{g}/\text{mouse}$   $1,25(\text{OH})_2\text{D}_3$ , indicating that inecalcitol was 480 times less calcemic than  $1,25(\text{OH})_2\text{D}_3$  [553]. Similar results were obtained following daily intraperitoneal injections for 7 days [555]. Inecalcitol treatment of mice inoculated with breast [552], SCC [554], and prostate [553] cancer cells demonstrated a marked reduction in tumor growth with minimal calcemic effects.

### 7.2.3 Paricalcitol

Paricalcitol (19-nor- $1,25(\text{OH})_2\text{D}_2$ ) has been approved by the US Food and Drug Administration for the clinical treatment of secondary hyperparathyroidism. Studies by several groups have demonstrated that paricalcitol has antiproliferative and prodifferentiation activities against myeloid leukemia and myeloma cell lines at clinically achievable concentrations [140,556,557]. Paricalcitol activity was dependent on the presence of VDR, as it was unable to induce differentiation of mononuclear bone marrow cells from VDR-KO mice, whereas cells from WT mice were differentiated toward monocytes/macrophages [140]. Furthermore, paricalcitol was able to inhibit tumor growth without causing hypercalcemia in immunodeficient mice [140].

### 7.2.4 Doxercalciferol

This is a synthetic  $1\alpha(\text{OH})\text{D}_2$  vitamin  $\text{D}_2$  analog that undergoes metabolic activation in vivo to form  $1\alpha,25$ -dihydroxyvitamin  $\text{D}_2$  ( $1\alpha,25(\text{OH})_2\text{D}_2$ ). It has been commonly used since 1999 for the treatment of secondary hyperparathyroidism, chronic kidney disease, and metabolic bone disease (reviewed in Refs. [550,558]). Doxercalciferol inhibited tumor growth in a xenograft model of retinoblastoma with less toxicity than  $1,25(\text{OH})_2\text{D}_3$  [559]. It also synergizes with other compounds and can induce cell death of hepatocellular carcinoma cells [560] and apoptosis of ALL [561] and AML cells [477] in vitro.

### 7.2.5 PRI-1906 and its derivatives

The vitamin  $\text{D}_2$  analogs (24E)-(1S)-24-dehydro-24a-homo- $1,25$ -dihydroxyvitamin  $\text{D}_2$  (PRI-1906) and (24E)-(1S)-24-dehydro-24a,26,27-trihomo- $1,25$ -dihydroxyvitamin  $\text{D}_2$  (PRI-1907) with side chains extended by one (C-25 dimethyl) and two (C-25-diethyl) carbon units, respectively, displayed markedly elevated antiproliferative and differentiation-inducing activity in AML cells compared with  $1,25(\text{OH})_2\text{D}_3$  [37,562]. PRI-1906 and PRI-1907 underwent further 19-nor modification of the A-ring resulting in the PRI-5201 and PRI-5202 analogs, respectively [563], or 24Z (24-cis) modification in the

extended side chains giving the PRI-1916 and PRI-1917 analogs [564]. The 19-nor modification of PRI-1906 and PRI-1907 greatly enhanced their potency against AML cells [549,565], while the 24-cis (24Z) modification had an opposite effect [546]. The potency of PRI-1916 was slightly higher or equal to that of PRI-1906, while PRI-1917 was significantly less potent than PRI-1907 [546]. While PRI-1906 is substantially less calcemic than  $1,25(\text{OH})_2\text{D}_3$ , the much stronger differentiation inducer PRI-1907 is also much more toxic [565]. Interestingly, the 19-nor derivative of PRI-1906 (PRI-5201) exhibited only a slightly elevated calcemic effect in mice compared with its precursor, whereas the 19-nor modification of PRI-1907 greatly reduced the calcemic activity of the resulting PRI-5202 analog [144,565].

If reproduced in other systems, these data will support the hypothesis that the anticancer and calcemic activities of VDDs are regulated separately and, perhaps, independently as a result of complex interactions between the A-ring and side-chain structural moieties of VDDs and the ligand binding domain (LBD) of the VDR [566,567].

### 7.2.6 Derivatives of lithocholic acid

It has been documented that VDR has an important role in detoxification of xenobiotics and some endogenous compounds in the organism [568]. In particular, VDR binds potentially toxic metabolites of bile acids, such as lithocholic acid (LCA), which can activate this receptor and induces transcription of selected genes, including that encoding the detoxifying enzyme CYP3A4. Interestingly, in contrast to  $1,25(\text{OH})_2\text{D}_3$ , LCA did not stimulate the expression of the intestinal calcium channel TRPV6 in mice, and thus did not induce hypercalcemia [569]. Whether a similar selectivity exists in humans should be further investigated, since LCA analogs were able to upregulate TRPV6 gene transcription in a human intestinal cell line [570]. Recently, some LCA analogs were reported to be potent inducers of cell differentiation, with relatively low calcemic activity [570–572].

## 7.3 Potential mechanisms by which vitamin D analogs have increased biological activity

It has been speculated that, when compared with  $1,25(\text{OH})_2\text{D}_3$ , synthetic vitamin D analogs have several potential advantages for the treatment of human disease and may be of clinical use [541,548,573,574]:

- structure-dependent dissociation between enhanced antiproliferative and differentiation-inducing effects and reduced calcemic activity;
- reduced affinity to the serum vitamin D-binding protein;

- decreased catabolism by 24-hydroxylase;
- retention of biological activities by metabolic products of VDDs;
- increased stability of the ligand–VDR complex;
- increased dimerization with RXR $\alpha$  associated with increased affinity for VDREs in the promoters of target genes;
- enhanced recruitment of the DRIP coactivator complex.

It is also possible that different VDDs activate different signaling pathways, but it is still not clear how this would be achieved. However, there are likely to be cell type–specific differences in these mechanisms, and none of the aforementioned VDD features has been firmly established.

## 7.4 VDDs in combination with other agents

The concentrations of VDDs required to inhibit proliferation and/or induce differentiation of neoplastic cells in culture have the potential toxicity *in vivo*. Thus, various attempts have been made to lower the effective doses of VDDs through their combinations with other compounds that may act synergistically or additively yet have an acceptable toxicity. Particularly, the idea of administering VDDs either as adjuvants or as integral part of conventional chemotherapy has long attracted much interest [556,575,576]. Initial studies demonstrated a marked synergistic induction of differentiation in AML cell lines by low concentrations of 1,25(OH) $_2$ D $_3$  combined with the synthetic glucocorticoid dexamethasone [577] or the vitamin A derivative ATRA [43]. Since that time, numerous reports have shown that VDDs are capable of cooperating with various agents in experimental models of cancer (reviewed in Refs. [576,578,579]), and in some clinical studies described in the following. Here, we describe VDD cooperation with cytotoxic and cytostatic drugs, differentiation inducers, inhibitors of signaling kinases, anti-inflammatory agents, and phytochemicals.

### 7.4.1 Cytotoxic and cytostatic drugs

A number of preclinical studies have shown that VDDs potentiate cytotoxicity of chemotherapeutic agents in various cancer cell types, including AML cells, whereas such cytotoxic and cytostatic drugs can enhance the differentiation-inducing activity of VDDs (reviewed in Refs. [576,578]). For instance, enhanced growth arrest and cytotoxicity was demonstrated using combinations of VDDs with 1- $\beta$ -D-arabinofuranosyl cytosine (AraC; cytarabine) and other cytotoxic drugs ([580,581]. Some studies have suggested that the sequence of administering the compounds may be important [580,582]. For example, pretreatment with

etoposide enhanced the subsequent differentiation-inducing action of 1,25(OH) $_2$ D $_3$ , but pretreatment with 1,25(OH) $_2$ D $_3$  had little effect on the cytotoxic activity of etoposide. The potentiating effect of etoposide was associated with upregulation of VDR both at the miRNA and protein levels [582].

Further, it was proposed that DNA damage-induced elevation of VDR levels in etoposide- and doxercalciferol-treated non–small-cell carcinoma and osteosarcoma cells is mediated by p73, but not by p53. VDR upregulation was accompanied by sensitization of the cells to 1,25(OH) $_2$ D $_3$  treatment [583]. Studies using AML cell lines and patient-derived blasts have shown that the combinations of 1,25(OH) $_2$ D $_3$  or doxercalciferol and the plant polyphenol carnosic acid (CA) added following AraC-treatment selectively increased its cytotoxicity to AML blasts, but not to normal bone marrow cells [471,472]. The enhanced cell death was associated with upregulation of VDR in cells with DNA damage [472] without enhancing AraC-induced generation of reactive oxygen species (ROS) [584].

Both 1,25(OH) $_2$ D $_3$  [585] and paricalcitol [556] potentiated the growth-inhibitory and cytotoxic effects of As $_2$ O $_3$  on AML cells [405]. This drug has been successfully used for the treatment of APL, particularly when combined with ATRA [586,587]. The antiproliferative effect of paricalcitol/As $_2$ O $_3$  combination on NB4 human APL cells and U937 cells was associated with a decrease in the levels of the VDD-metabolizing enzyme 24-hydroxylase (CYP24A1) [556]. In another study, 1,25(OH) $_2$ D $_3$  was found to enhance the apoptotic activity of nutlin-3a, an inhibitor of p53-MDM2 interaction, in AML cells expressing wild-type p53 (MOLM-13 and OCI-AML3) by suppressing antiapoptotic protein BCL-2 and p90RSK and by inducing the proapoptotic protein PIG-6 [28]. Several reports described the ability of 1,25(OH) $_2$ D $_3$  to cooperate with epigenetically active compounds, such as the demethylating agent 5-aza-2'-deoxycytidine [588] and the histone deacetylase (HDAC) inhibitor sodium butyrate [589]. These and studies described in the following exemplify the still not totally explored potential of combining VDDs with other compounds.

### 7.4.2 Retinoids

The fact that the VDR and the RXR $\alpha$  interact to form a heterodimeric transcription factor [590] suggests that VDDs and retinoids, both being potent differentiation inducers, can cooperate in producing anticancer effects. Indeed, synergistic or additive prodifferentiation and antiproliferative activities of 1,25(OH) $_2$ D $_3$  combined with ATRA or 9-cis retinoic acid (9-cis-RA) have been reported in various cancer cell types including AML cells (reviewed in Refs. [27,578]). In most studies, AML cells treated with 1,25(OH) $_2$ D $_3$ /retinoid combinations

displayed a monocytic phenotype, though granulocytic or mixed phenotypes were also described depending on the particular cell subtype and concentrations of each inducer (e.g., Refs. [578,591]). Monocytic differentiation of 1,25(OH)<sub>2</sub>D<sub>3</sub>/ATRA-treated myeloblastic AML cells or normal myeloid progenitors was concomitant with the direct repression of ATRA transcriptional activity by 1,25(OH)<sub>2</sub>D<sub>3</sub> [592]. This effect was attributed to the formation of dominant-negative VDR-containing complexes bound to the promoters of ATRA target genes, such as the retinoic acid receptor beta (RAR $\beta$ ) gene. In contrast, 1,25(OH)<sub>2</sub>D<sub>3</sub> potentiated ATRA-induced granulocytic differentiation in APL cells, and this was associated with the enhancement of ATRA-induced transactivation of the RAR $\beta$  promoter [593]. The combination of ATRA with 1,25(OH)<sub>2</sub>-16-ene-23-yne D<sub>3</sub> cooperatively decreased c-MYC expression [594]. Interestingly, U937 cells exposed to a moderate thermal stress responded with increased differentiation after the addition of 1,25(OH)<sub>2</sub>D<sub>3</sub> and ATRA, suggesting that induction of heat shock protein may be sequestering a protein that may favor proliferation or differentiation [595]. The induction of M2 macrophage-like phenotype in AML cells by 1,25(OH)<sub>2</sub>D<sub>3</sub>/retinoid combinations has been reported [194]. The retinoids tested were 9-cis-RA, ATRA, or the synthetic RAR $\alpha$  agonist Am80. All these combinations promoted macrophage-like morphological changes and increased the expression of M2 macrophage markers, such as CD163, ARG1, and IL-10. RAR $\alpha$  agonist (AGN195183) was effective in driving neutrophil differentiation of NB4 cells, and this agonist synergized with a low concentration of 1,25(OH)<sub>2</sub>D<sub>3</sub> to drive monocyte differentiation of NB4 and KG1 cells [596].

#### 7.4.3 Protein kinase C activators

Other differentiation inducers, such as PKC activators 12-O-tetradecanoylphorbol-13-acetate (TPA) [597,598] and bryostatin-1 [599], were found to synergize with VDDs in the induction of AML cell differentiation and growth arrest. For instance, Bhatia et al. reported that the combination of 1,25(OH)<sub>2</sub>D<sub>3</sub>, TPA, and M-CSF resulted in a synergistic response in NB4 cells, causing a complete differentiation to fully functional adherent macrophages with a rapid arrest of cell growth in the first 24 h [597]. Using cDNA microarrays and Northern blot analyses, it has been shown that the synergistic induction of macrophage-like differentiation of myeloblastic leukemia cells ML-1 by TPA and the 1,25(OH)<sub>2</sub>D<sub>3</sub> analog KH1060 was associated with an enhanced expression of several TPA target genes. These included tryptase  $\beta$ 1, BCL2A1, ATF3, CD14, FBP1, and PrP [598]. This illustrates that PKC (TPA activated) and MAPK (VDD activated) can synergize for an optimal differentiation of a hematopoietic cell type [598].

#### 7.4.4 Antiinflammatory agents

VDDs have antiinflammatory activity [600,601]. Nonsteroidal antiinflammatory drugs (NSAIDs) enhance the differentiation of HL60 cells in response to 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs [602,603]. This effect may occur because of a block of NF- $\kappa$ B activation. Using a panel of AML cell lines and patient-derived blasts, it was shown that different COX1/2 inhibitors markedly potentiated 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced cell differentiation and G0/G1 cell cycle arrest through the RAF1-dependent mechanism [604]. It was also demonstrated that 5-lipoxygenase inhibitors can enhance 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation of HL60 cells in a p38 MAPK-dependent manner [605].

#### 7.4.5 Kinase inhibitors

Specific inhibitors of p38 MAPK (SB203580 and SB202190) were found to accelerate monocytic differentiation of HL60 cells induced by low concentrations of 1,25(OH)<sub>2</sub>D<sub>3</sub> [603,606]. This augmented potency was associated with a prolonged activation of the JNK and, to a lesser extent, the ERK pathways. Recently, specific inhibitors of the MEK5/ERK5 MAPK signaling pathway were found to cooperate with VDDs, promoting a macrophage-like phenotype, enhancement of phagocytic activity, and growth inhibition in AML cells in vitro and ex vivo [33,50]. This was associated with the upregulation of the M-CSFR and was not seen when M-CSFR expression was knocked down. Inhibition of glycogen synthase kinase-3 (GSK3), e.g., by SB415286, potentiated the differentiation response of AML cell lines to low concentrations of 1,25(OH)<sub>2</sub>D<sub>3</sub> and augmented the ability of 1,25(OH)<sub>2</sub>D<sub>3</sub> to induce cell growth inhibition in vitro and in vivo [607]. Mechanistic studies revealed that GSK3 inhibition increased the transcriptional activity of VDR, which resulted from receptor phosphorylation leading its enhanced coactivator, SRC-3 [607]. Inhibition of mTORC1 by the rapamycin analog everolimus potentiated the growth-inhibitory and differentiation-inducing effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> in U937 cells both in vitro and in vivo [181]. The addition of everolimus enhanced 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated transcriptional activation of p21<sup>Cip1</sup> expression, which apparently was associated with increased levels of VDR bound to the p21<sup>Cip1</sup> (CDKN1A) promoter.

#### 7.4.6 Phytochemicals

A number of phytochemicals (aka “botanicals”) have been reported to enhance differentiation of AML cells induced by VDDs (reviewed in Ref. [578]). Among these are the plant polyphenolic antioxidants carnosic acid (CA), curcumin, and silibinin [473,608,609] and sesquiterpene lactones [610]. The potential therapeutic

significance of such combinations was supported by the findings that CA preparations and low calcemic VDDs synergistically inhibited leukemia progression in mouse models [611,612]. The mechanisms underlying the aforementioned cooperative effects involve modulation of various cellular systems. Thus, CA has been shown to upregulate VDR/RXR $\alpha$  expression and functional activity, which may explain the increased sensitivity of cancer cells to lower doses of VDDs [473]. These effects were mediated by the activation of the NRF2/antioxidant response element (NRF2/ARE) signaling pathway and AP-1 transcription factor [143,613]. Based on these findings, it was demonstrated that other structurally distinct NRF2 activators, including dimethyl fumarate (Tecfidera) approved for the treatment of multiple sclerosis, were capable of synergistically enhancing VDD-induced differentiation of AML cells. Further, combined treatment with DMF and the highly potent vitamin D<sub>2</sub> analog PRI-5202 cooperatively inhibited leukemia progression in a xenograft model of AML in vivo [144].

Interestingly, silibinin was found to modulate the differentiation effects of VDDs in a cell type-dependent manner. While enhancing the differentiation in the HL60 and OCI-AML3 cell lines and leukemic blasts from some patients with AML, it had no effect or even inhibited the differentiation of the MOLM-13 and U937 cell lines and primary blasts from other patients [191,404,613,615], which may reflect the different mutations that are present in these cells. The positive influence of this polyphenol was associated with the upregulation of transcription factors of the JUN and C/EBP families [614], whereas its negative effects with the inability to activate NRF2/ARE as well as with downregulation of RXR $\alpha$  expression [613] and activation of the oncogenic COT1/TLP2 and ERK5 kinases [191]. Other signaling kinases, such as ERK1/2 and JNK MAPK and PKC [259,609], were shown to positively contribute to the differentiation-enhancing effects of various phytochemicals. On the other hand, the tumor suppressor p53 status in AML cells did not affect the differentiation-associated G1 cell cycle arrest induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> combined with CA or silibinin [404], while miRNA-181a was found to antagonize doxercalciferol/CA-induced cell differentiation and cell cycle arrest [615]. In addition, combinations of three agents, including 1,25(OH)<sub>2</sub>D<sub>3</sub> and either the p38 inhibitor SB202190 plus CA [616] or the COT1/TLP2 inhibitor 4-(3-chloro-4-fluorophenylamino)-6-(pyridin-3-yl-methylamino)-3-cyano-[1,2,3,4,5,6,7]-naphthyridine plus silibinin [191] further potentiated the antileukemic activity against AML cells and primary AML blasts.

In summary, treatment of leukemia or MDS with a VDDs is unlikely, by itself, to be successful, but when given either in the maintenance phase of therapy after the leukemic patient is placed into remission or

combined with other agents, vitamin D compounds may be useful therapeutically. Furthermore, 1,25(OH)<sub>2</sub>D<sub>3</sub> can induce the expression of the antimicrobial peptide CAMP [617], which may afford the cancer patient some protection from life-threatening infections while receiving aggressive chemotherapy.

## 7.5 Clinical trials of VDDs in hematopoietic malignancies

As discussed before, encouraging results of numerous preclinical studies with VDDs, alone and in combination, against AML cells provided the basis for clinical trials of these agents. However, the attempts to utilize the prodifferentiation and antiproliferative properties of VDDs in clinic have had so far minimal success, possibly due to the variable levels of VDRs in the malignant cells, the heterogeneity of AML subtypes, and sub-optimal design of clinical trials (reviewed in Refs. [618–620]). More trials of VDDs in hematological malignancies are being conducted (examples are shown in Table 86.4), but outcomes at this time are unclear. Despite several examples of promising clinical efficacy of VDDs, there are three major concerns: (1) The lack of definition of a sensitive target subset of AML patients because clinical trials conducted so far have generally used extremely heterogeneous patient populations and, in many cases, small numbers of patients, often without controls. (2) The still unknown optimal choice of a vitamin D analog and the dosing schedule. (3) No coherent mechanistic basis for the claimed improved therapeutic window. Further, since different dosage and time schedule of compound administration were used, it is not possible to directly compare the VDD effects on the diseases studied. The results of clinical studies of several VDDs are provided below.

### 7.5.1 1,25(OH)<sub>2</sub>D<sub>3</sub> and 25(OH)D<sub>3</sub>

Treatment of elderly MDS patients having moderate/severe anemia with the combination of erythropoietin with 1,25(OH)<sub>2</sub>D<sub>3</sub> and 13-cis retinoic acid resulted in a long-lasting (7 years) erythroid response in the majority of MDS patients with unfavorable prognostic features for response to erythropoietin alone [624]. In patients with MDS and AML treated with 1,25(OH)<sub>2</sub>D<sub>3</sub> in combination with cytarabine, 6-thioguanine, and 13-cis-retinoic acid, the response rate was 50%, with 27% complete remission [625]. The combination of 1,25(OH)<sub>2</sub>D<sub>3</sub>, AraC, and hydroxyurea resulted in complete or partial responses in 79% of elderly patients with AML [626]. These regimens had acceptable toxicity. A recent study evaluated a 4-year maintenance therapy with low-dose cytotoxic agents combined with 1,25(OH)<sub>2</sub>D<sub>3</sub> and 13-cis retinoic acid in poor-prognosis

**TABLE 86.4** Selected clinical trials of VDDs in hematological malignancies during the years 2015–21.

Study number	Condition/disease	Compound	Aim of the study	Age group; enrolment	Phase	Status
NCT02802267	AML	I-cal	Efficacy study of I-cal in combination with decitabine in patients unfit for standard chemotherapy	65–75; 110	II	O
NCT03176849	HSCT	25(OH)D <sub>3</sub>	Safety and efficacy of a single, high dose of oral vitamin D; the start of transplant followed by maintenance supplementation in children undergoing HSCT	<3–>12; 49	IV	C <sup>a</sup> [621,622]
NCT00068276	MDS	25(OH)D <sub>3</sub>	Efficacy in terms of hematological improvement, in patients with low- or intermediate-risk of MDS (the effect on disease symptoms, fatigue, and the overall health-related quality of life)	Any; 36	II	C
NCT00104806	MDS	25(OH)D <sub>3</sub>	Determination of the complete response rate and the rate of hematological improvement in patients with MDS treated with arsenic trioxide and 25(OH)D <sub>3</sub>	Any; 26–60	II	T
NCT00064376	MDS	P-cal	Determination of the clinical effects of P-cal in patients with MDS; its influence on the decrease the risk of development of leukemia without causing undue toxicity	>25; 20	II	C
NCT01787409	DLBCL/CML	25(OH)D <sub>3</sub>	The role of 25(OH)D <sub>3</sub> in improving survival in patients with newly diagnosed cancer and vitamin D insufficiency	>18; 713	N/A	O <sup>a</sup> [623]
NCT01521936	AML	25(OH)D <sub>3</sub>	Partially randomized studies on the side effects, administration route, and dosage of 25(OH)D <sub>3</sub> in AML patients undergoing intensive induction chemotherapy	>18; N/A	II	T
NCT02341495	AML	25(OH)D <sub>3</sub> Deferasirox Azacytidine	Study on a novel therapeutic combination of deferasirox, 25(OH)D <sub>3</sub> , and azacytidine in older patients with newly diagnosed AML who are unfit for standard chemotherapy or HSCT	>65; N/A	II	T
NCT02949570	CML	I-cal	To assess the efficacy of I-cal in combination with imatinib in CML patients with molecular residual disease on imatinib monotherapy	>18; 54	II	O
NCT00052832	MDS/CML	D-cal	Determination of the response rate, toxicity profile, and influence on overall survival	>18; 41	II	C

<sup>a</sup>Results published.

1,25(OH)<sub>2</sub>D<sub>3</sub>, 1 $\alpha$ ,25-dihydroxyvitamin D<sub>3</sub>; 25(OH)D<sub>3</sub>, 25-hydroxyvitamin D<sub>3</sub>; D-cal, doxercalciferol; DLBCL, diffuse large B-cell lymphoma; I-cal, inecalcitol; P-cal, paricalcitol; AML, acute myeloid leukemia; CML, chronic lymphoid leukemia; CLL, chronic lymphocytic leukemia; HSCT, hematopoietic stem cell transplant; MDS, myelodysplastic syndromes; C, completed; T, terminated; O, ongoing; N/A, not applicable.

elderly patients with AML and MDS [627]. This treatment resulted in a lower relapse incidence and a longer disease-free and overall survival compared with the control patients who did not receive maintenance treatment.

A combination treatment of elderly patients with AML with the 1,25(OH)<sub>2</sub>D<sub>3</sub> precursor 25(OH)D<sub>3</sub> and the iron-chelating agent deferasirox resulted in a significant increase in median survival in comparison with patients receiving best supportive care alone. Interestingly, the only factor associated with survival benefit was the serum 25(OH)D<sub>3</sub> level prior to treatment. Thus, the median overall survival of patients with normal 25(OH)D<sub>3</sub> levels ( $\geq 50$  nmol/L) was significantly higher compared with the group with what the authors considered to be vitamin D deficiency ( $\leq 50$  nmol/L) [628]. This study was based on the previous findings by this group [629] showing that combination of iron depletion and 1,25(OH)<sub>2</sub>D<sub>3</sub> enhanced the differentiation of both HL60 cells and AML primary blasts in vitro and suppressed the growth of HL60 xenografts in mice. Importantly, several other studies have also demonstrated that low levels of circulating 25(OH)D<sub>3</sub> were associated with shorter survival, worse prognosis, and adverse outcomes in newly diagnosed and treated patients with MDS [630], AML [630,631], CLL [632], and follicular lymphoma [536].

### 7.5.2 Synthetic vitamin D analogs

Several VDDs have been studied as potential therapy for patients with MDS, leukemias, and lymphomas, as described in the following.

#### 7.5.2.1 Alfalcidol

Among the early attempts, beginning in the 1980s, to demonstrate the therapeutic value of VDDs were Japanese studies of alfalcidol, an analog that only requires 25-hydroxylation in vivo to promote VDR activation (e.g., Ref. [633]). Leukemic transformation-free survival was monitored in patients with MDS treated with 4–6 µg/day alfalcidol (per os) for 17 months or placebo [633]. An improvement of hematologic parameters was detected in only one patient, though leukemia-free survival and AML incidence of the treated group had significant advantage over the control group. These results suggested that oral administration of alfalcidol may prevent the progression of MDS to overt leukemia. A multicenter prospective phase II clinical trial of vitamin K2 (approved in Japan for osteoporosis treatment [634] and shown to ameliorate cytopenia in MDS [635]) and its combination with oral alfalcidol (0.75 µg daily) was conducted for 16 weeks in patients with low-risk MDS [636]. The results demonstrated that the combination was more effective than vitamin K2 alone in improving anemia and thrombocytopenia. In a small-scale pilot study, patients with low-grade

non-Hodgkin's lymphoma were treated with 1 µg oral alfalcidol daily [637]. Patients with the follicular small, cleaved, subtype achieved complete or partial remission, whereas none of patients with small lymphocytic lymphomas responded. This analog is currently rarely studied in relation to malignant diseases.

#### 7.5.2.2 Inecalcitol

Inecalcitol has been tested in a phase II trial in patients with CLL at a daily dose of 2 mg. The results demonstrated that 52% of patients experienced stabilization or decrease of blood leukemic lymphocytes counts [638]. An exploratory phase II study of inecalcitol (4 mg daily) is ongoing in older CML patients under treatment with imatinib (EU Clinical Trials Register: 2014–004347-12). In addition, a randomized phase II efficacy trial of inecalcitol in combination with decitabine has been initiated in older AML patients unfit for standard chemotherapy (NCT02802267).

### 7.6 Paricalcitol and doxercalciferol

Small-scale clinical trials of oral paricalcitol [639] and doxercalciferol [640] were conducted in MDS patients. Although paricalcitol was well tolerated in all patients at doses of 8–56 µg/day, it had only minimal activity against MDS [639]. Other clinical trials have demonstrated that it has reduced calcemic activity [641,642]. Patients who received 12.5 µg/day doxercalciferol, for 12 weeks, did not develop hypercalcemia, but they also did not obtain a clinical response [640].

## 8. Significance of basic and clinical studies of VDDs in hematopoietic malignancies: from bench to bedside

As discussed before, the encouraging results of numerous preclinical studies of VDDs alone and in various combinations against hematopoietic malignancies provided the basis for clinical studies and formal clinical trials of these agents.

There are numerous reports of an association between suboptimal levels of 25(OH)D<sub>3</sub> and the prevalence of hematopoietic malignancies, including monoclonal gammopathies such as multiple myeloma (MM) [643–646]. Vitamin D deficiency also appears to predict adverse outcome, such as poor overall patient survival, in several hematopoietic malignancies, including MM [647], intensively treated adult AML [631], MDS and secondary oligoblastic AML [630], as well as follicular lymphoma [536].

Supporting these associations, several examples of potentially promising clinical efficacy of VDDs in hematopoietic malignancies have been published. The

ex vivo cytotoxic activity of myeloma-associated macrophages can be enhanced by vitamin D supplementation [648], and VDR function is necessary for the inhibition of growth of all plasmablastic cell lines that were studied [649]. This may also explain that VDR polymorphisms are associated with several cancers including MM, and 25(OH)D insufficiency can be demonstrated in those individuals [650–652].

Several, more direct, clinical studies showed that supplementation of MM patients with VDDs can positively influence the prognosis of monoclonal gammopathies. For example, the administration of cholecalciferol (approximately 10,000 IU/week) significantly increased the patients' hemoglobin levels, the erythrocyte and leukocyte counts [643]. Oral 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation (0.25 µg TID for 30 days) of patients with MM and Hodgkin's and non-Hodgkin's lymphoma following autologous stem cell transplantation significantly shortened lymphocyte count recovery, and the relapse-free survival was significantly better [494]. However, the attempts to utilize the prodifferentiation and antiproliferative properties of VDDs in the clinic have had so far minimal success, possibly due to the variable levels of VDRs in the malignant cells, the heterogeneity of the subtypes of AML and other malignant hematopoietic disorders, and suboptimal design of clinical trials including the dosage of VDDs used (reviewed in Refs. [618–620]). By August 16, 2021, an impressive number (3471) of clinical studies with vitamin D<sub>3</sub> or its analogs were recorded in the [clinicaltrials.org](https://clinicaltrials.org) database, and 447 of these studies were at that time recruiting patients (examples are shown in Table 86.4) [3,621,623,653]. Of note, few of the terminated trials had potentially positive outcomes, and many were closed because of poor patient accrual or loss of financial support. However, as a number of trials are still recruiting patients, positive outcomes cannot yet be excluded ([www.clinicaltrials.gov](https://www.clinicaltrials.gov)). Further, since various dosages and schedules of compound administration were tested in different trials, there is still no agreement on the safe dosages of VDDs that exhibit anticancer properties and do not cause hypercalcemic side effects, and it is not possible to directly compare the VDD effects on the diseases studied.

But before abandoning all hope for the potential of VDDs in the management of hematopoietic malignancies, the clinical trials design needs to be improved. The main problem with the inconspicuous results of clinical trials that have been terminated is likely that concentrations of the VDDs used have been too low. There is now a slowly increasing realization among health providers that the maximal dosage of VDDs for producing antineoplastic effects is much higher than the concentrations needed for its bone health effect, but this realization needs to reach the regulatory

agencies. Thus, if frequent determinations of patients' serum calcium levels can be factored into the trial protocol, there seems to be no reason that at least 4000 IU of vitamin D daily should be a part of the treatment cocktail. Such off-label use of vitamin D may be helpful in compassionate situations, but the analysis and the publication of the results are likely to be problematical [27,630,631].

## 9. Conclusions

It is clear that the physiological forms of vitamin D have important roles in human health, including the development of the normal hematopoietic system, and the still not totally fulfilled promise as a tool to combat hematopoietic malignancies. Regarding the latter, the search for VDDs that dissociate calcium mobilizing properties in vivo from differentiation-inducing, antiproliferative, or cell death-enhancing properties continues. However, it seems likely that the combinations of existing low-calcemic analogs with nontoxic compounds, which potentiate vitamin D–derived antineoplastic effects, may reach the clinic sooner than the new analogs. Yet, both of these will require greater investment of effort and funding than has recently been available. Nonetheless, the hematopoietic cells appear to be well poised to provide exciting results necessary to further increase the credibility to vitamin D and cancer field.

## 10. Summary points

- VDDs are powerful differentiating agents that target diverse cell types, but the physiological role of 1,25(OH)<sub>2</sub>D<sub>3</sub> in development remains to be fully determined.
- The presence of VDR is strictly required for VDD-induced monocyte/macrophage differentiation of AML cells.
- VDDs induce time- and cell type–dependent modulation of myeloid leukemia cell growth, with an initial proliferative burst followed by cell cycle arrest, and generally increase cell survival.
- The immunomodulatory role of 1,25(OH)<sub>2</sub>D<sub>3</sub> is beneficial in leukemias and in acute infections.
- Clinical trials of 1,25(OH)<sub>2</sub>D<sub>3</sub> at concentrations that do not cause hypercalcemia are unlikely to have any therapeutic effect in leukemia patients.
- The complex relationships between the actions of VDDs on differentiation, the retardation of cell cycle progression, and cell survival of leukemic blasts require intensive study.

- An understanding of the complex actions of VDDs should allow a rational design of agent combinations that synergize with VDDs for clinical trials of therapy of MDS and leukemia.
